Abstract

Should exchange rate policy communication be transparent or intentionally opaque? We show that it depends on whether expectations depart from rationality. We develop a macroeconomic model in which agents overreact to their private information about fundamentals and use the exchange rate as a public signal to learn about the private information of others. In this environment, central bank communication surrounding foreign exchange (FX) interventions can influence the information content of the exchange rate and can be used to “manage expectations.” While FX interventions that are publicly announced provide additional information about fundamentals, secret FX interventions instead alter the informational content of the exchange rate. If the overreaction bias is strong enough, it is optimal to intervene secretly to limit the informativeness of the exchange rate. Our model rationalizes observed practices in exchange rate policies such as managed floats and the opacity surrounding FX interventions.

Keywords: exchange rates, information frictions, foreign exchange interventions, central bank communication.

1 Introduction

Open economies experience recurrent episodes of capital inflows that result in large fluctuations of exchange rates and macro aggregates. Amidst these events, central banks regularly intervene by purchasing and selling currencies in the foreign exchange (FX) market.\(^1\)

Although the effectiveness and desirability of FX interventions are still debated, at least three observations point to an important role of public communication and information in FX markets. First, an increasing number of central banks reportedly believe that FX interventions work primarily by affecting market expectations (Patel and Cavallino, 2019). Second, policymakers’ communication about FX interventions lacks transparency as interventions are often not publicly announced or only published with some lag (Canales-Kriljenko, 2003; Patel and Cavallino, 2019). These two observations suggest that publicly observed interventions convey information to market participants, and that central banks may be reluctant to disclose such information. Third, exchange rates, as market prices, play an informational role by aggregating agents’ knowledge and beliefs about economic fundamentals (Hayek, 1945; Grossman, 1976), an idea often evoked by policymakers and commentators.\(^2\) By affecting exchange rates, interventions may thus be used to influence markets’ expectations about those fundamentals. While seemingly important in practice, these channels remain relatively unexplored in state-of-the-art macro models of FX interventions.

This paper develops a macroeconomic model to formalize the informational role of the exchange rate and derive its implications for the conduct and communication about FX interventions. We show that FX interventions have an information channel that depends on the transparency of central bank communication. Our central message is that the optimal conduct of FX interventions depends on how expectations are formed.

\(^1\)While primarily utilized by emerging economies, in recent decades FX interventions have been increasingly prominent also in advanced economies such as Switzerland and Japan (Adler et al., 2021). For example, the Swiss National Bank has spent 353 billion francs buying foreign currency since 2015, while the Bank of Japan intervened in September 2022 for the first time since the crisis of 1997-1998.

\(^2\)During a recent meeting of African central bank governors, IMF African Department Director Abebe Aemro Selassie highlights that “The exchange rate in most developing countries is the most visible and important price in the economy and so helps to anchor expectations, facilitate planning, as well as investment, and consumption decisions.” (Selassie, 2023). In interpreting a recent Euro depreciation episode, Financial Times Markets Editor Katie Martin writes that “The euro’s latest wobble also forms yet another big signal that investors think Europe’s luck has run out. The startling resilience in the euro area economy that supported the currency and made the region’s stocks such an unusual hot pick at the start of this year is clearly fading away.” (Martin, 2023).
If expectations are rational, it is optimal to intervene publicly, disclosing the amount of the FX intervention and the rule of the intervention. If expectations overreact to new information, transparent communication amplifies this bias, and secret interventions can be optimal instead. The model rationalizes a signaling channel of FX interventions as well as the opaqueness in many central banks’ practices.

Our dynamic small-open economy model has three distinctive features. First, international asset markets are segmented, which implies that financial flows directly influence equilibrium exchange rates and interventions are effective, as in Gabaix and Maggiori (2015) and Fanelli and Straub (2021). Second, information is dispersed in that each agent has access to a different piece of private information about the economy’s fundamentals. As a result, the exchange rate aggregates information and is used by agents to form expectations about future economic fundamentals, and thus to make consumption and investment decisions. The relaxation of the full-information assumption is the main departure from the previous literature that allows our model to speak to the informational role of exchange rates and FX interventions. Third, investors’ expectation formation process is subject to a cognitive distortion known as “over-extrapolation,” which induces them to over-react to new information. As a result, agents learn from the exchange rate – a public signal – but they over-react to such information.

All three features are well supported empirically. First, recent work on estimation of currency demand provides evidence of segmentation consistent with our model (see evidence reviewed in Maggiori, 2022). Second, recent work also supports the notion that exchange rates reflect, at least in part, available information about a country’s future fundamentals. In particular, Chahrour et al. (2022) show that a large portion of exchange rate variation emanates from anticipated changes in future productivity, with a significant component of expectational noise. Last, agents’ expectations “over-reaction” is also well documented in survey expectations data. Bordalo et al. (2020a) document that forecasters typically over-react to news about macroeconomic and financial variables, while Candian and De Leo (2023) show that expectations’ under- and over-reaction explains key properties of exchange rate dynamics.

The model formalizes a novel informational role of the exchange rate in macroeco-

---

3See also Engel and West (2005) and Stavrakeva and Tang (2020). In our model of dispersed information, “noise-trader shocks” blur the relationship between exchange rate and fundamentals and effectively act as noise in the public signal – the exchange rate – as in Bacchetta and Wincoop (2006).

4See also Angeletos et al. (2020).
nomic allocations. An equilibrium exchange rate appreciation, for example, leads to an upward revision of agents’ forecast of future fundamental, and, in turn, to higher consumption, investment, and external borrowing. The informational role of the exchange rate in macroeconomic allocation operates above and beyond the traditional expenditure switching and wealth effects. The strength of this mechanism hinges on the informational content of the exchange rate, which pertains to the degree to which the exchange rate reflects variations in future economic fundamentals. This is an equilibrium object in our model that, as we explain below, also depends on how exchange rate policy is conducted.

The informational channel of the exchange rate transmits through agents’ belief formation. It is thus central to ask whether agents use available information optimally when forming expectations. We show that expectations over-reaction to new information generates an independent inefficiency in the competitive equilibrium. More specifically, agents’ over-reaction to the informational content of equilibrium exchange rate causes excessive volatility in macroeconomic allocations. Ceteris paribus, the exchange rate is excessively volatile.

We demonstrate that the macroeconomic consequences of FX interventions not only depend on their size but also on the transparency of the communication surrounding them. If the volume of the FX intervention is publicly announced, it becomes an additional public signal about the private information of the central bank. Consequently, the intervention assumes a “signaling role,” which expands the information set available to economic agents. On the other hand, if the central bank does not announce the volume of the intervention, i.e., if it intervenes secretly, then it does not directly provide information to agents, but alters the information content of the exchange rate by changing its stochastic properties. For instance, if the central bank intervenes to partially offset the effect of noise trading on the exchange rate, akin to a specific form of “leaning against the wind,” the exchange rate becomes a better signal about fundamentals, and agents attach a larger weight to it when forming their expectations. By the same logic, if the central bank intervenes secretly to offset the effect of fundamentals on the exchange rate, it reduces the informational content of the exchange rate. As a result, secret FX interventions can be designed to either increase or decrease the information content of the exchange rate. The central bank can leverage the information channel and use FX intervention as a policy tool to “manage expectations.” We investigate the normative implications for the optimal conduct of FX interventions.
and find that it depends on how expectations are formed. In particular, it is not always welfare-maximizing for a central bank to increase the information available to agents. If expectations are rational, providing information is welfare-improving, as it lowers the expectation errors due to the information friction. As a result, it is optimal to intervene publicly and following a rule, i.e. disclosing the amount of the intervention as well as the central bank’s reaction function. On the contrary, if expectations display an over-reaction bias, more information may not always be welfare-improving, as agents use this information sub-optimally. In this case, secret interventions that let the exchange rate reflect some non-fundamental variation reduce its information content and help tame over-reaction. With secret interventions the central bank can thus optimally trade off inefficient capital flows and expectations over-reaction. We characterize this trade-off and the optimal policy across varying degrees of the extrapolation bias.

The model speaks to central aspects of real-world exchange rate policy. First, it offers an explanation for two seemingly contradictory empirical observations: policymakers reportedly believe that FX interventions work primarily by affecting market expectations, but their communication about FX interventions is often opaque (Sarno and Taylor, 2001; Patel and Cavallino, 2019). In our model, FX interventions indeed play an important signaling role. However, when expectations overreact to news, central banks may find it advantageous to conduct these interventions opaquely, thereby reducing the informational content of exchange rate fluctuations. Second, the model presents a novel interpretation of the widespread practice of “systematic managed floating” (Frankel, 2019): central banks regularly respond to changes in total market pressure, with a portion reflected in the exchange rate itself and the rest absorbed through changes in foreign exchange reserves. In our model, when expectations exhibit over-reaction, it becomes not only optimal for central banks to intervene secretly but also desirable to reduce the overall volatility in exchange rates, both fundamental and non-fundamental. This policy effectively lowers the equilibrium volatility of the exchange rate, an approach reflecting “fear of floating” (Calvo and Reinhart, 2002). The underlying rationale is that central banks aim to diminish the exchange rate’s role as an informative public signal in environments characterized by over-reaction.5

**Contribution to the literature** This paper contributes to several strands of literature in open-economy macroeconomics, international finance, and behavioral macroeconomics. Recent research by Bianchi and Coulibaly (2023) shows how “fear of floating” emerges in models featuring constraints on borrowing linked to exchange rate fluctuations.
First, this paper belongs to the open-economy literature on exchange rate policy, and especially recent work on the costs and benefits of FX interventions. In this literature, financial frictions in international capital markets are the main motive behind FX interventions (Gabaix and Maggiori, 2015; Ghosh et al., 2016; Cavallino, 2019; Fanelli and Straub, 2021; Amador et al., 2019; Itskhoki and Mukhin, 2022; Boz et al., 2020). Our paper argues that information frictions are at least as important in understanding the conduct of FX interventions.6

Second, our model of dispersed information builds on the seminal work of Grossman (1976) as well as the more recent work of Bacchetta and Wincoop (2006). We apply some of their insights to a general equilibrium framework where the informational role of the exchange rate affects macroeconomic allocations. Besides, we incorporate possible departures from rational expectations and study foreign exchange intervention policy.7 Gaballo and Galli (2022) also studies the information channel of central bank’s asset purchases, but in a closed economy setting where interventions are always publicly observed. Iovino and Sergeyev (2021) study the effects of central bank balance sheet policies in a model where people form expectations through an iterative level-κ thinking process, also in a closed economy and without information frictions.

Third, our analysis speaks to the literature on exchange rate policy under imperfect information. Kimbrough (1983, 1984) show that flexible exchange rate regimes allow agents to learn from the exchange rate, but only consider monetary policy. Vitale (1999, 2003) study the signaling role of FX interventions in a market micro-structure framework, where the central bank transparency is not about the size of the intervention but about its objective, i.e. the intervention rule. Fernholz (2015) also studies the implications of central bank transparency during foreign exchange interventions, but in a partial equilibrium setting where FX interventions affect fundamentals. We contribute to this literature by studying foreign exchange interventions in a unified general-equilibrium framework where financial markets are segmented, information is dispersed and there are possible departures from rational expectations (in the form of

6Another strand of this literature focuses on how different assumptions on currency pricing shape the optimal conduct of monetary policy in open economies. Prominent examples are Galí and Monacelli (2005), Benigno and Benigno (2003), Engel (2011), Devereux and Engel (2007), and Egorov and Mukhin (2020). These models assume full information rational expectations, and foreign exchange interventions are generally ineffective.

extrapolative expectations). We frame our normative analysis within a micro-founded loss function as opposed to relying on *ad hoc* policy objective functions.

Our paper also contributes to the debate on the social value of public information. A key lesson from this literature, highlighted in Angeletos and Pavan (2007), is that when economic fluctuations are driven primarily by shocks or other distortions that induce a countercyclical efficiency gap, it is possible that providing markets with information lowers welfare. These conditions may arise, for example, in the presence of markup shocks (Angeletos et al., 2016), distortionary taxes (Fujiwara and Waki, 2020), in the presence of sticky prices (Fujiwara and Waki, 2022), and even with supply shock if they are inefficiently shared across countries (Candidan, 2021). In our model, the reason why publicly announcing interventions achieves a lower welfare than keeping them secret is behavioral and is that agents overreact to the exchange rate. To our knowledge, we are the first to address the question of the social value of public information in a model with endogenous signals and departures from rationality.

Finally, this project relates to the growing body of work on central bank communication on monetary policy or financial stability. Prominent examples are Angeletos and Sastry (2020), Chahrour (2014), Kohlhas (2020), Melosi (2017), Blinder et al. (2008), Ehrmann et al. (2019), Born et al. (2014), Dávila and Walther (2022).

## 2 Model

We consider a two-period small-open economy model with a tradable sector and non-tradable sector extended to incorporate three features of interest. First, limited asset market participation gives rise to a finite elasticity of demand for foreign bonds and, therefore, a scope for foreign exchange interventions. Second, the economy is affected by two aggregate shocks that are imperfectly observed by agents in the economy: productivity shocks and “noise” shocks to the demand for foreign bonds. Finally, agents observe the exchange rate and learn from it.

### 2.1 Model setup

The small-open economy is populated by four types of agents: households, final-good producers, financiers, and a central bank. Households, final-good producers, and financiers are located on a continuum of atomistic islands, \( i \in [0, 1] \), as in Lucas (1972). Information is common within islands but heterogeneous across islands. In particular,
on each island, households and financiers receive the same private noisy signal on next-period productivity of the small open-economy. Agents observe local output and prices as well as the exchange rate, which serves as a noisy public signal about next-period productivity. Time is discrete and indexed by \( t = [0, 1] \). Foreign variables are denoted with a star symbol.

### 2.1.1 Households and goods markets

The preferences of the representative household of island \( i \) are described by the following utility function:

\[
\frac{C^i_0^{1-\sigma}}{1-\sigma} + \beta E_0 \left( \frac{C^i_1^{1-\sigma}}{1-\sigma} \right),
\]

where \( C^i \) denotes consumption and \( E_0 \) is an expectation operator, non necessarily rational and conditional on information set in \( t = 0 \).

Households have an initial endowment of capital, \( K^i_0 = K_0 > 0 \), which fully depreciated between periods and is used in the production of tradable goods:

\[
Y^i,H_{T,0} = K^i_0^\alpha, \quad Y^i,H_{T,1} = A_1 K^i_1^\alpha.
\]

Above, \( A_1 \) represents stochastic period-1 productivity. In each period, the household also receives an endowment of the non-tradable good: \( Y^i,N_{T} = (1 + \alpha \beta \gamma) Y^i,N_1 \).\(^8\) Consumption and period-1 capital are composites of tradable and non-tradable goods:

\[
C^i_0 + K^i_1 = G(Y^i,N_{T,0}, Y^i,T_{0}), \quad C^i_1 = G(Y^i,N_{T,1}, Y^i,T_{1})
\]

where \( G(Y_N, Y_T) = \left[ (1 - \gamma)^{\frac{1}{\theta}} Y_N^\frac{\theta-1}{\theta} + \gamma^{\frac{1}{\theta}} Y_T^\frac{\theta-1}{\theta} \right]^{\frac{\theta}{\theta-1}} \) is homogenous of degree 1. The parameter \( \theta \) denotes the elasticity of substitution between tradable and non-tradable goods in the production of final goods while \( \gamma \) governs the share of tradable goods in the final composite good. In (3), \( Y^i_{T,t} \) represents domestic absorption of the tradable good, which is the sum (difference) of production and imports from (exports to) the rest of the world \( Y^i_{T,t} = Y^i,H_{T,t} + Y^i,F_{T,t} \). We assume that each island trades with the rest of the world but not with other islands to avoid full information revelation by inter-island interactions.

\(^8\)This choice of relative endowment in period 0 and 1 is convenient as it delivers a steady state with \( B^*_1 = 0, Q_0 = Q_1 = 1 \) and \( C_0 = C_1 \).
Since the aggregator $G$ is homogenous of degree 1, we have, in equilibrium:

$$P_i^t G(Y_{N,t}, Y_{T,t}^i) = P_{N,t}^i Y_{N,t} + S_t P_{T,t}^* Y_{T,t}^i,$$  \hspace{1cm} (4)

where $P_i^t$ is the island-$i$ price of the composite good, and $P_{N,t}^i$ is the island-$i$ price of the non-tradable good. $S_t$ is the nominal exchange rate, which is common across islands. We assume that the foreign-currency price of tradable goods is constant and equal to 1, i.e. $P_{T,t}^* = P_T = 1$.

The price of the tradable good relative to the non-tradable good is given, in equilibrium, by their marginal rate of transformation:

$$\frac{S_t}{P_{N,t}^i} = \frac{\partial G(Y_{N,t}, Y_{T,t}^i)}{\partial Y_{T,t}^i} / \frac{\partial G(Y_{N,t}, Y_{T,t}^i)}{\partial Y_{N,t}} = \left( \frac{\gamma}{1 - \gamma Y_{T,t}^i} \right)^{\frac{1}{\theta}}.$$  \hspace{1cm} (5)

Combining this expression with (4) yields the equation determining island-$i$ composite price index:

$$P_i^t = \left[ (1 - \gamma) P_{N,t}^i \gamma^{-\theta} + \gamma S_t \gamma^{-\theta} \right]^{\frac{1}{1-\theta}}.$$  \hspace{1cm} (6)

Combining these last two equations we obtain the demand function for tradable goods:

$$Y_{T,t}^i = \chi \left[ \left( \frac{S_t}{P_i^t} \right)^{-\theta} \gamma - \gamma \right]^{\frac{\theta}{1-\theta}} Y_{N,t}$$  \hspace{1cm} (7)

with $\chi = \frac{\gamma}{(1-\gamma)^{\theta}}$. The household’s budget constraints are:

$$P_0^i C_0^i + P_0^i K_1^i + \frac{B_1^i}{R_0} = P_{N,0}^i Y_{N,0} + S_0^i Y_{T,0}^i + T_0^i$$

$$P_1^i C_1^i = B_1^i + P_{N,1}^i Y_{N,1} + S_1^i Y_{T,1}^i + T_1^i$$  \hspace{1cm} (8)

The date-0 budget constraint assumes no initial debt and states that the household’s income from the sale of tradable and non-tradable goods as well as from government nominal transfers, $T_0^i$, can be used to buy consumption goods, invest in physical capital, or save in a domestic nominal bond, $B_1^i$, whose interest rate is $R_0$. The date-1 budget constraint states that all the income of the household is used for consumption.

Implicit in (8) is the assumption of limited asset market participation. Specifically, we assume that the household cannot hold foreign bonds (e.g., Gabaix and Maggiori,
This assumption captures the idea that it is difficult for many households in emerging markets to access international financial instruments without financial intermediation, especially when borrowing in foreign currency.

Maximizing utility \((1)\) subject to the budget constraints in \((8)\) yields the following optimality conditions:

\[
\beta R_0 E_0 \left( \frac{C_1}{C_0} \right)^{-\sigma} \left( \frac{P_0^i}{P_1^i} \right) = 1 \quad (9)
\]

\[
\alpha \beta E_0^i \left( \frac{C_1^i}{C_0^i} \right)^{-\sigma} \frac{S_1^i}{P_1^i} A_1 K_i^\alpha = 1 \quad (10)
\]

Finally, using \((3)-(4)\) in the budget constraints \((8)\), island \(i\) households’ budget constraints simplifies to:

\[
\frac{B_1^i}{R_0} = S_0 (Y_{T,0}^H - Y_{T,0}^i) + T_0^i, \quad -B_1^i = S_1 (Y_{T,1}^H - Y_{T,1}^i) + T_1^i. \quad (11)
\]

where each island households leave no debt at the end of period 1.

### 2.1.2 Financial market

Financiers from every island trade home and foreign bonds in the small-open economy-wide financial sector. Along with financiers, the government and a set of noise traders also operate in the financial sector, as we describe next.

**Financiers** We assume that there are frictions in the financial sector which give rise to a downward-sloping demand for currency from the financiers. In particular, we follow the formulation of Fanelli and Straub (2021). In each island a continuum of risk-neutral financiers trade home and foreign bonds subject to position limits and facing heterogeneous participation costs, as in Alvarez et al. (2009).

In Appendix A.1, we derive the maximization problems of island-\(i\) financiers, and show that it results in the following demand for the foreign currency bond:

\[
\frac{D_1^i}{R_0^i} = \frac{1}{\Gamma} E_0^i \left( R_0^i - R_0 S_0 \right) \frac{S_0}{S_1}, \quad (12)
\]

where the zero-capital portfolio island-\(i\) financiers and their carry trade profits are,
respectively:
\[
\frac{D_i}{R_0} + S_0 \frac{D_i^*}{R_0^*} = 0, \quad \pi_{1,D}^* \equiv D_1^* + \frac{D_1}{S_1} = \cdots = \tilde{R}_1 \frac{D_1^*}{R_0^*}.
\]

Aggregating across islands, the overall demand of financiers for foreign bonds is:
\[
\frac{\int D_1^* \, d_i}{R_0^*} = \frac{1}{\hat{\Gamma}} \tilde{E}_0 \left( R_0^* - R_0 \frac{S_0}{S_1} \right). \tag{13}
\]

where \( \tilde{E}_0(X_t) \) denotes the average expectation of \( X_t \) across islands, i.e. \( \tilde{E}_0 X_t = \int E_0^i X_t \, d_i \).

Financiers’ demand for foreign bonds has a finite (semi-)elasticity to the expected excess return, implying that changes in the net supply of foreign bonds, e.g., induced by FX interventions, indeed affects the equilibrium exchange rate. The critical parameter in equation (13) is the inverse demand elasticity \( \hat{\Gamma} \), which governs the strength of frictions in the international financial market. If \( \hat{\Gamma} \) is large, e.g., due to tight position limits, intermediation is impeded. In the extreme case where \( \hat{\Gamma} \to \infty \) intermediation is absent, and foreign bond demand is nil. By contrast, when \( \hat{\Gamma} \to 0 \), bond demand adjusts so that expected excess foreign currency returns are nil, and the elasticity is infinite. Henceforth, we assume \( \hat{\Gamma} \in (0, \infty) \).

**Noise traders** Noise traders exogenously demand foreign currency \( \frac{N_1}{R_0} \). Here \( \frac{N_1}{R_0} > 0 \) means that noise traders short home-currency bonds to buy foreign-currency bonds. They also hold a zero-capital portfolio in home and foreign bonds denoted \((N_1, N_1^*)\), which implies:
\[
\frac{N_1}{R_0} + S_0 \frac{N_1^*}{R_0^*} = 0. \tag{14}
\]

**Central Bank/Government** The economy-wide central bank holds a \((F_1, F_1^*)\) bond portfolio. The value of the portfolio is \( \frac{F_1}{R_0} + S_0 \frac{F_1^*}{R_0^*} \). We assume that the government finances its operations with transfers:
\[
\frac{F_1}{R_0} + S_0 \frac{F_1^*}{R_0^*} = - \int T_i \, d_i, \\
0 = F_1 + S_1 F_1^* + \tau S_1 \left( \int \pi_{1,D}^* \, d_i + \pi_{1,N}^* \right) - \int T_i \, d_i, \tag{15}
\]
where $\pi_{i,D}^* \star$ is the income from financial transactions of financiers on island $i$, defined above, and $\pi_{N}^* \star$ is the income from financial transactions of noise traders.

**Financial market clearing** Since home-currency bond are in zero net supply, market clearing implies

$$\int B_i^i \, di + N_1 + \int D_i^i \, di + F_1 = 0. \tag{16}$$

Combining the market clearing condition with households and government budget constraints, and the portfolios and income from financial transactions of financiers and noise traders, we obtain the aggregate position of the financiers, in foreign currency:

$$\frac{\int D_i^i \, di}{R_0^*} = \int \left( Y_{i,T}^{i, H} - Y_{i,T}^{i, 0} \right) \, di - \frac{F_1^* + N_1^*}{R_0^*}. \tag{17}$$

That is, the aggregate position of financiers equals the portion of households’ bond demand – originating from the trade imbalance – that is not met by the foreign currency supplied by the government and noise traders.

### 2.2 Equilibrium characterization

#### 2.2.1 Economy-wide exchange rate

As standard in the literature, we solve the model using a log-linear approximation around a steady state with $A = 1, N^* = F^* = 0$ and $B^i = D^i = 0 \forall i$. In Appendix A.2 we report the island-level equilibrium, and in A.3 we derive the solution for the equilibrium aggregate real exchange rate as a function of shocks and expectations thereof:

$$q_0 = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} (n_1^* + f_1^*) - \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \bar{E}_0 a_1 \tag{18}$$

where $\bar{E}_0$ is the average expectation across all islands and and $\omega_1 > 0, \omega_2 > 0, \omega_3 > 0$, and $\tilde{\theta} > 0$ are convolutions of parameters independent of $\Gamma$.

The first term of equation (18) describes how shocks to the demand for foreign bonds by noise traders and central bank induce an exchange rate depreciation, for a given level of expectations about future fundamentals. To see the mechanism at play, note that higher demand for foreign bonds by noise traders and/or central bank requires financiers to take a short position on foreign bonds (eq. (A.8)). To do so, financiers require a compensation in proportion to $\Gamma$ (A.7): the real exchange rate
depreciates today, so that its expected appreciation guarantees financiers an expected profit on their long domestic bond position. For completeness, the exchange rate depreciation also induces an increase in the price of tradable goods, leading to lower import and reduced borrowing. The resulting decline in households’ demand for more domestic bonds (eqs. (A.4) and (A.8)) alters the position of financiers and attenuates the equilibrium depreciation of the exchange rate.

The second term of equation (18) describes how an upward revision in expected future fundamental leads to an exchange rate appreciation, keeping the demand for bond of noise traders and central bank constant. First, a higher future technology implies a higher future supply of tradable relatively to non-tradable goods, implying a reduction in the future relative price of tradables, i.e. a future exchange rate appreciation (A.4). By uncovered interest parity, the exchange rate today appreciates (eq. (A.7)). In terms of financial flows, a reduction in the equilibrium price of tradables leads households to increase their import and borrowing, issuing domestic bonds to financiers. Correspondingly, financiers take a short position on foreign bonds and long on domestic bonds, they require an expected exchange rate appreciation (A.7), which attenuates today’s equilibrium exchange rate appreciation resulting from the expected improvement in future fundamentals.

2.2.2 Discussion of assumptions

Before we move on, let us discuss some of the assumptions that we made.

First, we have distributed agents along a continuum of islands that do not directly interact with one another other than through a common financial market. Allowing for further interactions among all islands (for example, via inter-island goods trade) would completely reveal average expectations and, therefore, eliminate any marginal informational role of aggregate public signals, may those be aggregate prices such as the exchange rate or quantities such as interventions.

Second, we have assumed that there is only one aggregate price that agents observe, namely the exchange rate, but two economic disturbances, productivity shocks and noise-trading shocks. This assumption ensures that agents cannot fully back out the aggregate state of the economy by simply observing the exchange rate.\(^9\)

\(^9\)While the nominal interest rate of the small-open economy bond is also observable, we assume that agents do not use its information to infer the state of fundamentals. However, it is possible to microfound the uninformativeness of the nominal interest rate by having a local bond market and a local shock with an infinite noise, which averages to zero in the aggregate. In this setting, the resulting
These first two assumptions parsimoniously capture the idea that economic agents, for various reasons, do not perfectly observe all the variables that are relevant to their decisions but that they use easily accessible information, such as exchange rates, to improve their inference about such variables.

Third, we have assumed that financial intermediaries are owned by the household. This assumption ensures that the profits and losses from carry trade activity do not represent a net benefit or cost to the small-open economy. The implications of FX interventions of “leakages” from carry trade if financial intermediaries were owned by foreigners have already been studied by Fanelli and Straub (2021). Instead, we focus on the informational role of exchange rates and FX interventions.

Fourth, we have assumed that the small open economy can save in foreign bonds and physical capital. The presence of physical capital plays an important role in our model. The exchange rate, by affecting the relative demand for tradable and non-tradable goods, is a key determinant of the allocation of domestic income between domestic spending and external savings, as can be seen from (7)-(8). The breakdown of domestic spending between current consumption and capital investment depends on the expected marginal product of capital and thus on the expectation of future fundamentals, as embedded in (9)-(10). Absent capital, there is a one-to-one relationship between external saving and current consumption, and that relationship is entirely governed by the current exchange rate. Thus, a policymaker that is interested in affecting the path of consumption has no reason to influence expectations if it can directly affect the exchange rate. The presence of capital ensures that, for a given level of the exchange rate, expectations are a concern for the policymaker because they determine the allocation of domestic spending between current consumption and investment, or (in part) future consumption.

2.3 Laissez-faire information structure

We now consider how expectations are formed and introduce two important assumptions: dispersed information and extrapolative expectations. In particular, we highlight the informational role of the exchange rate and its equilibrium determination. In this section, we discuss the laissez-faire economy, that is the economy without FX interventions, $f_1 = 0$. We then introduce FX intervention policy in Section 3. Under laissez-faire, the equilibrium exchange rate is:

island-level interest rate would carry no information about aggregates.
\[ q_0 = \frac{\Gamma\omega_1}{\Gamma\theta\omega_1 + \omega_3} n^*_1 - \frac{\omega_2}{\Gamma\theta\omega_1 + \omega_3} \bar{E}_0 a_1. \]  

(19)

**Dispersed information**  Households and financiers in each island \( i \in [0,1] \) can observe local fundamentals, prices, and quantities, in addition to a local signal about the future realization of the technology shock \( a_1 \):

\[ v^i = a_1 + \epsilon^i, \quad \epsilon^i \sim N(0, \beta_{\epsilon}^{-1}), \]  

(20)

with \( \int \epsilon^i \, di = 0 \) and common prior \( a_1 \sim N(0, \beta_{a}^{-1}) \).

While agents in each island cannot observe aggregate prices and quantities, they share the same currency and can therefore observe the aggregate real exchange rate \( q_0 \) given in (18). The aggregate exchange rate is an important endogenous signal because it carries information about the aggregate expectation of the common future technology shocks \( a_1 \). Last, agents cannot directly observe the amount of noise trading (\( n^*_1 \)).

**Extrapolative expectations**  Consistent with growing empirical evidence (Bordalo et al., 2020b), we consider the possibility that agents do not form beliefs rationally, but have an extrapolation bias that causes them to over-react to new information. First, we follow (Bordalo et al., 2020b) in that agents extrapolate their private signal \( v^i \)

\[ E^i[a_1|v^i] = (1 + \delta)E^i[a_1|v^i] \]  

(21)

where \( E \) is the rational expectation operator and the parameter \( \delta \geq 0 \) governs the degree of extrapolation.\(^{10}\)

Second, because aggregate prices reflect average beliefs about fundamentals, agents in every island, when extracting information from the exchange rate, inherently need to forecast the forecast of agents in other islands. We thus need to specify how agents form these “higher-order beliefs.” We assume that agents are unaware not only of their own extrapolation bias, but also about the bias of all the other agent in the economy. In other words, they think of themselves and every other agents are rational. As a result, they interpret the endogenous public signal, i.e., the exchange rate, as aggregating

\(^{10}\)This setting can be viewed as a special case of the “diagnostic expectations” framework, with i.i.d. shocks and prior beliefs equal to zero (Bordalo et al., 2020a). However, while (Bordalo et al., 2020a) only consider exogenous private signals, we show how overreaction to exogenous private signals endogenously leads to overreaction to endogenous public signals.
rational instead of actual beliefs. That is, agents perceive the exchange rate pricing equation to differ from the actual pricing equation given in (18), and to be

\[ \tilde{q}_0 = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} n_1^* - \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \mathbb{E}[a_1 | v^i, \tilde{q}_0] \]  

(22)

where \( \mathbb{E}[a_1 | v^i, \tilde{q}_0] \equiv \int_i \mathbb{E}[a_1 | v^i, \tilde{q}_0] \, di \). Hereafter, we refer to \( \tilde{q}_0 \) as determined by equation (22) as the “perceived exchange rate process.” We show in the next section that this higher-order belief formation bias leads endogenously to overreaction to the public signal as well.

Finally, note that the special case of rational expectations corresponds to \( \delta = 0 \). In this case, not only agents do not extrapolate private information, but they are also correct in assuming that the other agents do not extrapolate either.

### 2.4 Learning from the exchange rate

The equilibrium exchange rate solves the fixed point problem of clearing the bond market given expectations and determining expectations given market clearing (and the rest of the equilibrium) conditions. To solve for the equilibrium exchange rate in terms of the underlying structural shocks, we adopt the method of undetermined coefficient. However, what determines expectations is not the actual but the perceived exchange rate process. As a result, we conjecture an equilibrium perceived exchange rate equation, derive the resulting average beliefs and then verify that it satisfies condition (22). Then we use the equilibrium perceived exchange rate process to derive the actual beliefs, and the actual equilibrium exchange rate.

#### 2.4.1 Perceived exchange rate process

We conjecture that the equilibrium perceived real exchange rate process depends linearly on the future fundamental \( a_1 \) and the noise trader shock \( n_1^* \)

\[ \tilde{q}_0 = \lambda_a a_1 + \lambda_b n_1^*, \]  

(23)

We now define the equilibrium under the laissez-faire information structure.

\[ ^{11} \text{Bastianello and Fontanier (2022) also study mislearning from prices, but starting from a different psychologically-founded bias. They consider agents who fail to understand that other agents learn from prices as well. In our setting, agents understand that other people learn from prices as well, but fail to internalize their overreaction bias.} \]
Definition 1 (Market equilibrium under laissez-faire). Given shocks realization \( \{a_1, n_1^*\} \) and agents’ prior and signals \( \{v^i, \tilde{q}_0\}_{i=0,1} \), a symmetric linear market equilibrium is defined as

- an allocation \( \{c_{i0}^i, c_{i1}^i, k_{i1}^i, y_{i1}^i, y_{i1}^i, b_i^1, d_i^1\}_{i=0,1} \)
- a vector of prices \( \{q_0^i, r_0^i\}, \{p_i^0, p_i^1\}_{i=0,1} \)
- A perceived real exchange rate as a linear function of the states \( \tilde{q}_0 = \lambda_a a_1 + \lambda_b n_1^* \), solving equations (A.2)-(A.8) and (22) with expectations respecting (21).

The perceived exchange rate process depends on aggregate expectations about the fundamental, but it is itself an information source for agents when forming their beliefs. As a result, the relation between the perceived exchange rate and the two shocks, governed by \( (\lambda_a, \lambda_b) \), is determined as the solution of a fixed point problem. In particular, one can rewrite (23) as

\[
\frac{\tilde{q}_0}{\lambda_a} = a_1 + \frac{\lambda_b}{\lambda_a} n_1^*. \tag{24}
\]

In this formulation, \( \frac{\tilde{q}_0}{\lambda_a} \) represents an unbiased signal centered around the fundamental shock \( a_1 \) with an error variance of \( \beta_q^{-1} = \frac{\lambda_a^2}{\lambda_a^2} \beta_n^{-1} \).

To sum up, agent \( i \) has access to three sources of information: (i) the prior distribution of \( a_1 \); (ii) the private signal (20); (iii) the perceived exchange rate process (24). Each agent thinks of the other agents as rational conditioning on these three signals, meaning their posterior belief is the average of the signals weighted by their accuracy

\[
\mathbb{E}^i[a_1|v^i, \tilde{q}_0] = \frac{\beta_v v^i + \beta_q \tilde{q}_0}{D}, \tag{25}
\]

where \( D \equiv \beta_v^2 + \beta_a^2 + \beta_n^2 \) is the posterior belief accuracy. We can average posterior beliefs \( \mathbb{E}[a_1|v^i, \tilde{q}_0] \equiv \int \mathbb{E}^i[a_1|v^i, \tilde{q}_0] \, dv^i \) using \( \int v^i \, dv = a_1 \) and substitute back in the perceived exchange rate process (22) to verify the conjecture (23). The following proposition characterizes the unique equilibrium of the model economy.

Proposition 1. Let \( \Lambda \equiv \frac{\lambda_a}{\lambda_v} \). The symmetric linear market equilibrium is unique and the perceived exchange rate process is described by (23) with coefficients

\[
\lambda_a = -\frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_v + \Lambda^2 \beta_n}{\beta_a + \beta_v + \Lambda^2 \beta_n}, \tag{26}
\]

\[
\lambda_b = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_v + \Lambda^2 \beta_n}{\beta_v}. \tag{26}
\]
where $\Lambda^2$ is unique and implicitly defined by

$$
\Lambda^2 = \left(\frac{\omega_2}{\Gamma \omega_1}\right)^2 \frac{\beta_v^2}{(\beta_a + \beta_v + \Lambda^2 \beta_n)^2}
$$

(27)

while the explicit solution of $\Lambda$ is reported in Appendix D.

Proof. See Appendix D. \qed

2.4.2 Actual exchange rate process

We can now use the equilibrium perceived exchange rate process to derive the actual agent’s belief and therefore the actual equilibrium exchange rate. First, agent $i$ forms belief using three sources of information: (i) the prior distribution of $a_1$; (ii) the private signal (20); (iii) the exchange rate. However, agents do not update rationally but suffer from two biases. First, they extrapolate private information as in (21). Second, they wrongly perceive the exchange rate process as following (23). Agent $i$’s posterior is

$$
E_i^i \equiv E^i[a_1|v^i, q_0] = \frac{(1 + \delta)\beta_v v^i + \beta_q \frac{q_0}{\lambda_a}}{D}
$$

(28)

We can average posterior belief $\bar{E}[a_1|v^i, \tilde{q}_0] = \int E^i[a_1|v^i, \tilde{q}_0] d\tilde{i}$ and plug in the actual equilibrium exchange rate equation (18). The actual equilibrium exchange rate follows

$$
q_0 = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_v}{\beta_v + \Lambda^2 \beta_n} n_1^* - (1 + \delta) \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_v + \Lambda^2 \beta_n}{\beta_a + \beta_v + \Lambda^2 \beta_n} a_1
$$

(29)

**Endogenous extrapolation** It is useful to compare the perceived and actual exchange rate processes to understand the bias that this misconception introduces in agents’ beliefs. Consider the actual public signal in agent’s posterior (28)

$$
\frac{q_0}{\lambda_a} = (1 + \delta) a_1 - \frac{1}{\Lambda} n_1^*
$$

(30)

If $\delta = 0$, there is no extrapolation bias and the perceived coincides with the actual exchange rate process. However, $\delta > 0$ leads to a misinterpretation of the endogenous public signal. First, while agents form belief under the impression that they are using an unbiased signal about the fundamental $a_1$, i.e (24), they are actually using a biased
signal, i.e. (30). This is a result of their belief bias in forming higher-order beliefs. Since agents overreact to their own private signal, the aggregate belief loads more on the average private signal, and therefore on the fundamental, by \((1 + \delta)\). However, as agents do not internalize this effect, they perceive the exchange rate as loading less on the fundamental \(a_1\) than the actual exchange rate. This leads agents to extrapolate the information about fundamental shocks contained in the exchange rate. Intuitively, they think of movement in the exchange rate as coming from large movements in the fundamental, while they are instead smaller movements amplified by the aggregate extrapolation \((1 + \delta)\).

Second, the perceived accuracy of the public signal equals the actual accuracy. In other words, while agents misperceive the mean of the public signal, they correctly perceive its accuracy. The reason is that the higher-order belief bias from \(\delta > 0\) does not affect how the exchange rate depends on noise shock \(n_{1\ast}\).\(^{12}\)

To sum up, since agents are unaware that the other agents in the economy suffer from extrapolation bias, they underestimate the covariance between exchange rate and fundamental shock, and as a result overreact to its information content. If \(\delta = 0\), there is no extrapolation bias and perceived coincides with actual exchange rate process.

### 2.5 The informational role of the exchange rate

Proposition 1 describes how the equilibrium exchange rate depends on the two shocks and therefore how informative it is about the fundamental shock, \(\beta_q \equiv \Lambda^2 \beta_n\).\(^{13}\) However, the informational role of the exchange rate not only depends on its own accuracy, but also on its accuracy relative to that of the other signals. The higher its relative accuracy compared to the other signals, the higher the weight agents assign to it when forming beliefs.

**Definition 2** (Relative information content of the exchange rate). Define the relative information content of the exchange rate as its relative accuracy as a signal about the fundamental shock \(a_1\) compared to prior and private signal. That is, the Bayesian

\(^{12}\)This result is due to the particular structure of the diagnostic expectation bias (Bordalo et al., 2020a), which affects only the posterior belief mean but not the posterior uncertainty. A belief bias on the perceived accuracy of private signals, e.g. overconfidence, would affect also the perceived accuracy of the endogenous public signal, as in Broer and Kohlis (2022).

\(^{13}\)As explained in the previous section, the perceived and actual exchange rate processes have the same loading on the noise shock \(n_{1\ast}\), and therefore the same accuracy as public signal. Therefore, the considerations laid down in this section apply similarly to the rational and extrapolative setting.
weight on public signal: $\mathcal{I}_R = \frac{\Lambda^2 \beta_n}{\beta_a + \beta_v + \Lambda^2 \beta_n}$. 

Now, let’s examine two limit cases that illustrate the contrast between the absolute and relative accuracy of the exchange rate as signal. To begin with, consider a scenario where private signals hold no informative content. In such a case, there is no dispersion of information, as all participants possess identical, incomplete information.

**Corollary 1** (Incomplete information economy). In the case of perfectly inaccurate private signals, $\beta^v \to 0$, the exchange rate coefficients equal $\lambda_a = 0$ and $\lambda_b = \frac{\Gamma \omega_1}{\Gamma \omega_1 \omega_2 + \omega_3}$. The relative information content of the exchange rate is nil, i.e. $\mathcal{I}_R = 0$ and the overall posterior accuracy is nil, i.e. $D = 0$.

If agents have no private information, the exchange rate has no private information to aggregate and therefore it will also be uninformative. Both the absolute and relative accuracy of the exchange rate are nil, as the common prior is the only source of information.

Next, consider the case where agents receive perfectly informative signals, and thus they are perfectly informed.

**Corollary 2** (Full Information economy). In the case of perfectly accurate private signals, $\beta^v \to \infty$, the exchange rate coefficients equal $\lambda_a = -\frac{\omega_2}{\Gamma \omega_1 \omega_2 + \omega_3}$ and $\lambda_b = \frac{\Gamma \omega_1}{\Gamma \omega_1 \omega_2 + \omega_3}$. The relative information content of the exchange rate is nil, i.e. $\mathcal{I}_R = 0$, while the overall posterior accuracy is infinite, i.e. $D \to \infty$.

Because the private signal is perfectly informative, the exchange rate – albeit a perfectly-revealing signal – does not provide additional information to agents. As a result, its absolute informativeness is positive, but its relative informativeness is zero.

More generally, the information contribution of the exchange rate is to aggregate individual beliefs. Therefore if the information is commonly shared among agents, the exchange rate does not provide any additional information to agents. This happens both in the case where agents are fully informed (Corollary 2) and in the case where the only information they have is their common prior (Corollary 1).

Away from these two limiting cases, the exchange rate has an informational role, as illustrated in Figure 1, in addition to the standard expenditure switching and wealth channels. One can re-write the exchange rate as

$$q_0 = z \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} n^*_i - z \left[ \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} (1 + \delta) \frac{\beta^v}{\beta_a + \beta_v + \Lambda^2 \beta_n} \right] a_1, \quad z \equiv 1 + \frac{\Lambda^2 \beta_n}{\beta_v} \ (31)$$
Figure 1: Information content of the exchange rate for different degrees of dispersed information

Notes: This figure reports the equilibrium value of the information content of the exchange rate for different levels of the noise in private signal, $\sigma_v$, under laissez faire. The rest of parameters are set as follows: $\beta = 0.99$, $\alpha = 0.3$, $\gamma = 0.3$, $\theta = 1$, $\sigma = 1$. The standard deviation of $a_1$ is $\sigma_a = 3$, while the standard deviation of $n^*_1$ is $\sigma_n = 3$. We consider two values for the over-reaction parameter, $\delta = [0; 0.5]$. The “No learning from FX” scenario corresponds to a parametrization of $\sigma_v = \infty$.

In order to highlight the informational role of the exchange rate, we examine the model responses to a decline in noise-trader demand for foreign currency ($n^*_1 < 0$, with $a_1 = 0$) as depicted in column 2 of Figure 2.

To begin with, consider a case in which agents do not use the exchange rate as a signal about fundamentals (i.e., $E_i^0 a_1 = \frac{\beta_v a_1}{\beta_v + \beta_a}$, and therefore $I_R = 0$, $z = 1$ in eq. (A.44)). In this case, $n^*_1 < 0$ causes an appreciation of the exchange rate through portfolio balance ($q_0 < 0$) and, in turn, results in higher consumption and investment. The noise-trading shock only operates through intermediation frictions and its impact on the exchange rate is the same as under full information, $\frac{\Gamma_{\omega_1}}{\Gamma_{\omega_1} + \omega_3}$. The red lines in column 2 of Figure 2 report the equilibrium responses of this model case.

Then, consider the baseline case in which agents learn from the exchange rate ($I_R > 0$, and $z > 1$ in eq. (A.44)), as depicted by the black lines in column 2 of Figure 2. Agents in each island observe the exchange rate appreciation, but they do not know whether it results from an expected increase in future fundamental ($a_1 > 0$) or to a decline in non-fundamental noise-trading demand for foreign currency ($n^*_1 < 0$). Thus, they confound, at least in part, the effect of the noise-trading shock on the exchange rate with the effect of higher future productivity and revise their beliefs about future
fundamental upward, as described by (25). As a result, households decide to increase their consumption and investment, relative to the no-learning-from-FX case. This effect is analogous to an exogenous news shock, but it is due to the endogenous response of the exchange rate to the decline in foreign currency demand from noise traders.

This change in beliefs implies a second round of effects on the exchange rate, which appreciates more than in the no-learning-from-FX case. The rational confusion between noise trading and technology shock amplifies the equilibrium effects of noise-trading shocks on the exchange rate, as originally highlighted in Bacchetta and Wincoop (2006), and on macro aggregates, as we emphasize through our fully specified macro model. In Appendix B we elaborate on the dual role of noise trading, and show that the model reproduces the empirical findings of Chahrour et al. (2022) that a substantial portion of the exchange rate variation can be attributed to correctly anticipated changes in productivity and expectational “noise,” which influenced expectations of productivity but not the actual realization.

The informational role of the exchange rate is larger when the relative information content of the exchange rate \( I_R \) is larger, as agents assign a larger weight to the exchange rate in their belief formation. The solid lines in Figure 2 report the equilibrium responses of the model under different levels of noise in the private signal \( \sigma_v \). As we consider cases closer to the common information economy characterized in Corollary 1 and 2, where \( \sigma_v \) approaches zero or infinity, the exchange rate ceases to be an informative public signal and its information effect becomes zero.

We stress that the information channel of the exchange rate described here does not rely on expectations over-reaction, and is operative even under rational expectations (\( \delta = 0 \)). Yet, expectations over-reaction changes the quantitative role of the information channel, as depicted in Figures 1 and 2 under \( \delta = 0.5 \). Because of expectations over-reaction, agents not only confound the noise-trading shock for a fundamental one, but they over-react to this information. As a result, they assign a larger-than-rational informational role to the exchange rate, and thus equilibrium variables exhibit an amplified response relative to the rational expectation case.

We have described the information channel conditional on a noise-trading shock. However, this channel is in place every time agents use the exchange rate as a signal about future fundamentals. In column 1 of Figure 2 we report the equilibrium responses of the model conditional on an increase in future productivity, \( a_1 > 0 \). The full-information economy response can be seen under \( \sigma_v = 0 \). In this case, agents perfectly
**Figure 2: Equilibrium responses to shocks for different degrees of dispersed information**

**Notes:** This figure reports the equilibrium value of model variables for different levels of the noise in private signal, $\sigma_v$, under laissez faire. The rest of parameters are set as follows: $\beta = 0.99$, $\alpha = 0.3$, $\gamma = 0.3$, $\theta = 1$, $\sigma = 1$. The standard deviation of $a_1$ is $\sigma_a = 3$, while the standard deviation of $n^*_1$ is $\sigma_n = 3$. We consider two values for the over-reaction parameter, $\delta = [0; 0.5]$. The “No learning from FX” scenario corresponds to a parametrization of $\sigma_n = \infty$.

foresee that productivity will increase, and they respond accordingly. They resort to external borrowing to increase current consumption and investment (and thus smooth consumption). When $I_R > 0$ (and $\delta = 0$), agents’ signal about future productivity is
imprecise and they use the exchange rate to learn about it.

3 Foreign Exchange Interventions

We now introduce the possibility for the central bank to intervene in the foreign exchange market by purchasing foreign-currency bonds $f_1^*$. We assume that FX interventions follow:

$$f_1^* = \kappa_b n_1^* + \kappa_a \bar{E}_0[a_1],$$

which we assume is known to agents.\(^{14}\)

We assume that the central bank, as an aggregate agent, is able to observe aggregate quantities and prices, and therefore the average expectation $\bar{E}_0[a_1]$. From average expectation and the exchange rate, it can back out the actual realization $a_1$, meaning that the central bank has superior information compared to individual agents.\(^{15}\) However, agents understand that the information source of the central bank is the average belief, and therefore the higher-order belief bias applies to the interpretation of the central bank’s FX intervention as well.

FX interventions are intermediated by financiers, analogously to noise-trading demand. In this model, FX interventions are effective, i.e. can affect the exchange rate, because they alter the balance-sheet position of financiers. For example, a central bank’s purchase of foreign bond $f_1^* > 0$ requires financiers to take an opposite position (long on domestic bonds and short on foreign ones). As a result, financiers require a compensation, so the real exchange rate depreciates today to allow a premium on financiers position ($18$). Besides, FX interventions may alter the information available to agents about future fundamentals, as we describe in detail below.

We consider two types of FX intervention communication policy. The first policy is public FX intervention, where the central bank communicates the volume of the FX intervention to the public, and thus $f_1^*$ becomes common knowledge. The second policy is secret FX intervention, where the central bank does not reveal the volume of the FX intervention. Nevertheless, the effect of the FX intervention is reflected in the exchange rate, and, by observing equilibrium exchange rates, agents form a forecast of

\(^{14}\)In appendix C, we derive the case in which FX interventions follow an exogenous process.

\(^{15}\)One could alternatively express the FX intervention rule in terms of the actual fundamental, $f_1^* = \hat{\kappa}_b n_1^* + \hat{\kappa}_a a_1 + \epsilon f_1^*$, as there is a linear mapping between the two sets of parameters: $\hat{\kappa}_a = \kappa_a (1 + \delta) \frac{\beta^a + \Lambda^2 \beta^b}{\beta^a + \beta^b + \Lambda^2 \beta^b}$ and $\hat{\kappa}_b = \kappa_b + \kappa_a \frac{\Lambda \beta^b}{\beta^a + \beta^b + \Lambda^2 \beta^b}$.
the FX intervention along with the forecast of the other aggregate variables.

3.1 Public rule-based FX intervention

Consider first the case in which agents are able to observe the aggregate volume of the FX intervention, \( f^*_1 \). Guess a linear solution for the (perceived) exchange rate process:

\[
\tilde{q}_0 = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} f^*_1 + \lambda_a a_1 + \lambda_b n^*_1, \tag{33}
\]

Define \( \hat{q}_0 \equiv \tilde{q}_0 - \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} f^*_1 \) as the equilibrium exchange rate, after the effect of the FX intervention is “partialed out.” Agents use the exchange rate as signal

\[
\frac{\hat{q}_0}{\lambda_a} = a_1 + \frac{\lambda_b}{\lambda_a} n^*_1, \tag{34}
\]

with a error variance of \( \beta_q^{-1} \equiv \frac{1}{\Lambda^2} \beta_n^{-1} \) with \( \Lambda \equiv \frac{\lambda_2}{\lambda_b} \), the same as in the laissez-faire economy (24). Regardless of the volume of FX intervention \( f^*_1 \), as long as it is observed it does not change the information content of the exchange rate.

However, the FX intervention carries independent information about the shocks to which it responds. In particular, the FX intervention becomes a public signal about the average expectations. In fact, rewrite (32) as:

\[
\frac{f^*_1}{\kappa_a} = \bar{E}_0[a_1] + \frac{\kappa_b}{\kappa_a} n^*_1. \tag{35}
\]

Agents can now access two public signals, the exchange rate (22) and the FX intervention (35), which are two independent functions of the same two components, \( \bar{E}_0[a_1] \) and \( n^*_1 \). As a result, agents are able to perfectly back out the average expectation \( \bar{E}_0[a_1] \) and therefore are perfectly informed.\(^{16}\) If agents are rational, they can perfectly back out the fundamental from average expectations, so that \( \bar{E}_0[a_1] = a_1 \). If \( \delta > 0 \), the average belief exhibits extrapolation bias: \( \bar{E}_0[a_1] = (1 + \delta) a_1 \).

In other words, with a transparent communication strategy by the central bank, the FX intervention has a signaling effect that increases agents’ information.

\(^{16}\)Consider the following linear combination of signals (34) and (22):

\[
\left( \frac{\lambda_a}{\lambda_b} \hat{q}_0 \frac{\Gamma \omega_1 + \omega_3}{\Gamma \omega_1} \right) / \left( \frac{\lambda_a}{\lambda_b} + \frac{\omega_3}{\Gamma \omega_1} \right). \text{ This signal would perfectly reveal } \bar{E}_0[a_1].
Corollary 3 (Public rule-based FX intervention). Suppose that $f_1^*$ is observable. The parameters $\kappa_b$ and $\kappa_a$ do not directly affect the accuracy of the exchange rate. However, the combined information of the FX intervention and the exchange rate perfectly reveals the average expectations $\hat{E}_0[a_1]$, so the economy is in full information. The relative information content of the exchange rate $I_R = 0$ and the overall agents’ posterior accuracy about fundamental $D \to \infty$. The equilibrium perceived exchange rate process is given by (A.22) with the same $\lambda_a = -\frac{\omega_2}{\theta_1 + \omega_3}$ and $\lambda_b = \frac{\Omega_1}{\theta_1 + \omega_3}$.

As the economy operates under full information, the exchange rate does not carry any additional information and thus it does not have any information channel. Since agents are fully informed, the actual exchange rate becomes

$$q_0 = \frac{\Gamma \omega_1}{\Gamma \theta_1 + \omega_3} (1 + \kappa) n_1^* - \frac{\omega_2 - \Gamma \omega_1 \kappa_a}{\Gamma \theta_1 + \omega_3} (1 + \delta)a_1.$$ (36)

When the future fundamental increases, $a_1 > 0$, in a laissez-faire economy (such as the one described by (22)) the exchange rate appreciates, $q_0 < 0$. The central bank can amplify this effect by selling foreign bonds, $\kappa_a < 0$, or dampen this effect (and even reverse it) by purchasing foreign bonds, $\kappa_a > 0$. If $\kappa_a = \frac{\omega_2}{\Gamma \omega_1}$, the central bank can completely offset the effect of fundamental on the exchange rate. Similarly, the central bank can amplify noise shocks by purchasing foreign bond when noise traders do, $\kappa_b > 0$, or dampen them (and even reverse them) by taking the opposite position $\kappa_b < 0$. If $\kappa_b = -1$, the central bank completely offsets the noise shocks by taking a symmetrical position.

Discussion Note that the result that public interventions lead to full information is due to our assumption that the central bank is able to observe average beliefs, which are then revealed by the volume of the FX intervention. We make this assumption to simplify the information extraction problem and the exposition. If the central bank had not superior but more generally different information with respect to agents, then public interventions would still increase agents’ information but only partially. Either way, the point is that transparent communication about FX interventions increase agents’ information about fundamentals by revealing the central bank’s information.
3.2 Secret rule-based FX interventions

Finally, consider the case in which the central bank does not reveal the aggregate volume of FX interventions, but still follows the rule described in (32). Substitute it in the exchange rate (18) and get

\[ q_0 = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} (1 + \tilde{\kappa}_b)n^*_1 - \frac{\omega_2 - \Gamma \omega_1 \tilde{\kappa}_a}{\Gamma \theta \omega_1 + \omega_3} \bar{E}_0 a_1. \]  

(37)

The unobserved FX intervention changes the structural relation between the exchange rate and the two shocks, and therefore the information content of the exchange rate. To solve the information problem, we guess a linear solution for the perceived exchange rate process

\[ \tilde{q}_0 = \lambda_a a_1 + \lambda_b n^*_1, \]  

(38)

which is the same guess as in the laissez-faire economy (23). However, since the exchange rate (37) is different, the equilibrium coefficients \( \lambda_a \) and \( \lambda_b \) are different as well.

**Proposition 2. (Secret rule-based FX Interventions)** Suppose the central bank adopts a secret rule-based FX intervention, i.e. \( f^*_1 = \tilde{\kappa}_b n^*_1 + \tilde{\kappa}_a \bar{E}_0 a_1 \) and \( f^*_1 \) is not directly observed. Then

\[ \lambda_a = -\frac{\omega_2 - \Gamma \omega_1 \tilde{\kappa}_a}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_v + \Lambda \beta_n}{\beta_a + \beta_v + \Lambda \beta_n}, \]

\[ \lambda_b = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} (1 + \tilde{\kappa}_b) \frac{\beta_v + \Lambda \beta_n}{\beta_v}, \]  

(39)

where \( \Lambda^2 \) is unique and implicitly defined by

\[ \Lambda^2 = \left( \frac{\omega_2 - \Gamma \omega_1 \tilde{\kappa}_a}{\Gamma \omega_1 (1 + \tilde{\kappa}_b)} \right)^2 \frac{\beta_v^2}{(\beta_a + \beta_v + \Lambda \beta_n)^2}, \]  

(40)

while the explicit solution of \( \Lambda \) is reported in Appendix D.

**Proof.** See Appendix D. \( \square \)

Substituting the actual average belief in (A.21), one gets the actual exchange rate

\[ q_0 = (1 + \delta) \lambda_a a_1 + \lambda_b n^*_1. \]  

(41)
Similarly to the public intervention case, the FX intervention alters the stochastic properties of the exchange rate, i.e. the structural relationship between the exchange rate and the underlying shocks. Differently from the public rule-based case, however, FX interventions are not observed and therefore they alter the information content of the exchange rate.

**Corollary 4.** The exchange rate accuracy \( \beta^q \equiv \Lambda^2 \beta^n \), its relative information content \( I_R \) and the overall posterior accuracy \( D \) are proportional to \((\omega_2 - \Gamma \omega_1 \bar{\kappa}_a)^2\), the correlation between exchange rate and fundamentals, and inversely proportional to \((1 + \bar{\kappa}_b)^2\), the correlation between exchange rate and noise shocks.

Intuitively, the more the exchange rate is correlated with the fundamental shock (relative to the noise-trading shock), the more information it carries about fundamentals. The central bank can, through FX interventions, increase the equilibrium covariance between exchange rate and fundamental, thereby increasing its information content and, as a result, the the overall amount of information in the economy.

We observe that secret FX policy can manage the information content of the exchange rate by appropriate choice of \((\kappa_a, \kappa_n)\). Figure 3 reports the equilibrium information content of the exchange rate for different values of the central bank’s reaction function \((\kappa_a, \kappa_n)\) under an illustrative calibration of the model with \(\delta = 0\). It is useful to highlight a number of interesting cases. First, the secret FX policy can attain the full-information equilibrium if it fully offset the noise trading variation in the exchange rate \((\kappa_n = -1)\). By doing so, the central banks renders the exchange rate a perfectly informative signal of future fundamentals. Second, the secret FX policy can engineer an equilibrium in which the exchange rate is uninformative, by fully offsetting the fundamental variation in the exchange rate (under \(\delta = 0\), this requires \(\kappa_a = \omega_2 / \Gamma \omega_1\)). Importantly, a special case of an uninformative equilibrium exchange rate is an exchange rate peg, which is obtained when the secret FX policy enforces a constant exchange rate by eliminating all noise and fundamental variation in the exchange rate.

As shown in Figure 3, outside of these two limit cases (fully informative and uninformative exchange rates), there is a spectrum of cases in which the exchange rate is an imperfect signal of future fundamentals, which can be achieved by appropriate choice of \((\kappa_a, \kappa_b)\). A special case of imperfectly informative exchange rate is an exchange rate (free) float. This regime coincides with the laissez-faire equilibrium, obtained when \(\kappa_a = \kappa_b = 0\). Under free floating, exchange rate fluctuations reflect both fundamental
and noise, and thus their information content is limited and constrained by the relative amount of noise in exchange rate fluctuations.\footnote{Hassan et al. (2022) explore how exchange rate policy influences the riskiness of that country’s currency, by altering the stochastic properties of the exchange rate, and derive the implications for optimal exchange rate policy. We also emphasize that FX policy affects the macroeconomic allocation by altering the stochastic properties of the exchange rate, yet through a distinct, complementary channel: the informativeness of the exchange rate.}

Overall, we emphasize that, unlike public FX interventions, secret FX interventions allow a central bank to “manage” the informativeness of the exchange rate. Relative to laissez-faire, secret FX interventions increase or reduce the information content of the exchange rate, depending on how they are conducted. In the next section, we explore whether the central bank may find desirable to intervene publicly or secretly.

Figure 3: Secret FX intervention and the information context of the exchange rate

Notes: The figure reports values of the information content of the exchange rate ($I_R$) for different values of the central bank’s reaction function ($\kappa_a, \kappa_n$) under secret FX intervention policy, for an illustrative calibration of the model under rational expectations (that is, $\delta = 0$).

4 Optimal Foreign Exchange interventions

4.1 Frictionless benchmark

Consider an economy without intermediation frictions, i.e. $\Gamma = 0$, and with full information and rational expectations, i.e. $E_0a_1 = a_1$. The frictionless equilibrium exchange
rate is
\[ q_{FB}^0 = -\frac{\omega_2}{\omega_3} a_1. \] (42)

The difference between the decentralized market equilibrium (18) and the frictionless allocation is
\[ q_0 - q_{FB}^0 = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} \left[ (n_1^* + f_1^*) + \frac{\tilde{\theta} \omega_2}{\omega_3} a_1 \right] - \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \left( E_0 a_1 - a_1 \right). \] (43)

There are two sources of inefficient fluctuations in the economy’s exchange rate. First, the intermediation wedge represents the suboptimal exchange rate variation due to the intermediation frictions in the bond market \((\Gamma > 0)\). The same term appears in the literature on models of FX interventions with intermediation frictions (Gabaix and Maggiori, 2015; Itskhoki and Mukhin, 2019, 2022). In this literature, FX intervention \(f_1^*\) is typically used to fully offset this term, unless there are other inefficiencies of the decentralized equilibrium. Second, a belief wedge emerges because of frictions in belief formation. It stems from the fact that average beliefs may not coincide with the true value of fundamental technology. The following proposition highlights that a benevolent social planner would need to address both wedges to achieve the frictionless allocation.

**Proposition 3.** Assume \(\theta \neq \sigma\). Then the frictionless allocation can be achieved only if \(E_0 a_1 - a_1 = 0\).

**Proof.** See Appendix D.

Proposition 3 means that engineering an intermediation wedge that exactly offsets a non-zero belief wedge is not enough to attain the frictionless allocation of the overall macroeconomic equilibrium. Intuitively, a non-zero belief wedge affects the broad macro allocation, including investment decisions. As explained in Section 2.2.2, a frictionless exchange rate only ensures that the allocation of domestic income between domestic spending and external savings is optimal. Nevertheless, if expectations of future technology are excessively optimistic, then the split of domestic spending between consumption and investment would be sub-optimal. For these reasons, the frictionless allocation can only be attained when both the intermediation wedge and the belief wedge are simultaneously zero.\(^{18}\)

\(^{18}\)This argument applies outside of the knife-edge case where the intertemporal elasticity of substi-
4.2 Belief wedge

The departure from the Full Information Rational Expectation Hypothesis introduces a wedge between the frictionless allocation and the decentralized equilibrium which we refer to as “belief wedge”, as discussed in Section 4.1. The belief wedge is proportional to the forecast error, which depends on the two frictions on beliefs: dispersed information and extrapolation. We now discuss how these two belief frictions affect the wedge and, in particular, the accuracy of the exchange rate signal \( \beta_q \equiv \Lambda^2 \beta_n \) affect the belief wedge. In the next section we show that FX interventions can also alter the accuracy of the exchange rate as a signal.

Rational expectations  Consider the case where agents have dispersed information but rational belief, i.e. \( \delta = 0 \). The individual forecast error unconditional variance equals

\[
\text{var}(E_i[a_1|v^i,q_0] - a_1) = \frac{1}{(\beta^v + \beta^q + \beta^a)} \tag{44}
\]

It is easy to see that in this case forecast errors, and therefore the belief wedge, are inversely proportional to the accuracy of public signal \( \beta_q \). Intuitively, higher information lowers forecast errors as long as agents use such information optimally. In other words, under rational expectations, a belief wedge emerges solely because of dispersed information. If dispersed information is resolved with a perfectly informative public signal (as under \( \beta_q \to \infty \)), then equilibrium average expectations are correct and the belief wedge is zero.

Corollary 5 (Belief wedge with rational expectations). With rational expectations \( \delta = 0 \), the unconditional variance of the individual forecast error on fundamental (44) is minimized with perfectly informative public signal \( \beta_q \to \infty \).

Extrapolative beliefs  Consider a more general case where agents have dispersed information but non-rational beliefs, i.e. \( \delta > 0 \). The individual forecast error unconditional variance equals

\[
\text{var}(E_0[a_1] - a_1) = \frac{[\delta(\beta^v + \beta^q) - \beta^a]^2}{(\beta^v + \beta^q + \beta^a)^2} \frac{1}{\beta^a} + \frac{(1 + \delta)^2 \beta^v + \beta^q}{(\beta^v + \beta^q + \beta^a)^2} \tag{45}
\]

\(\beta_v\) is the elasticity of substitution between tradable and non-tradable goods.
With extrapolative beliefs, the relation between forecast errors and public signal informativeness is more nuanced. If the exchange rate is perfectly accurate \( \beta^q \to \infty \), we are in full information but the consensus error variance is positive, \( \text{var}(\hat{E}_0^i a_1 - a_1) = \delta^2 \frac{1}{\beta^q} \). Even if the information content of the exchange rate is very precise, agents overreact to this information due to their extrapolation bias. As a result, the belief wedge is positive even in full information.

More generally, for large enough extrapolative bias \( \delta \), higher public signal precision has two opposite effects on the belief wedge. First, like in the rational expectation case, higher precision provides more information, lowering the belief wedge. Second, higher precision increases the relative weight on the public signal in posterior belief, and therefore it amplifies the extrapolation bias, increasing the belief wedge. We show the first effect prevails for low values of signal accuracy, while the second effect prevails for larger values of accuracy. As a result, the wedge is minimized for an interior solution of public signal accuracy.

**Proposition 4** (Belief wedge with extrapolative expectations). If \( \delta < \bar{\delta} \), then the unconditional variance of the individual forecast error on fundamental (45) is minimized with perfectly informative public signal \( \beta^q \to \infty \). If \( \delta > \bar{\delta} \), then the unconditional variance of the individual forecast error on fundamental (45) is minimized with \( \beta^q = (\beta_a + \beta_v) \frac{1-2(1+\delta)}{1-2\delta(1+\delta)} > 0 \), where \( \bar{\delta} \equiv \frac{1+\sqrt{3}}{2} \).

**Proof.** See Appendix D.

To conclude, the notion that more information reduces the volatility of the belief wedge applies to the rational expectation setting, but not to the extrapolative beliefs setting. In that case, higher information might increase forecast errors as agents use information suboptimally. As a result, a perfectly informative public signal is not optimal anymore. In the next section, we study how different communication strategies in FX interventions can alter the information content of the exchange rate.

### 4.3 FX interventions and macroeconomic wedges

In this section, we turn to how FX interventions affect the macroeconomic equilibrium. In particular, we discuss how public and secret rule-based FX interventions impact the intermediation and the belief wedges described in Section 4.1. We highlight that providing information is welfare-improving in the rational expectation case, yet reducing
information may be welfare-improving in the case of extrapolative beliefs. We postpone a detailed characterization of the welfare-maximizing FX policy to Section 4.4.

**Rational expectations** First, consider a public, rule-based intervention. A public intervention perfectly reveals the information of the central bank, which in this case is full information (Proposition 3). Moreover, with rational expectation and full information, the belief wedge is zero (Proposition 5). As a result, the central bank can use the FX intervention to close the only wedge left, the intermediation wedge:

\[(1 + \kappa_b)n^*_1 + \left(\frac{\theta_2}{\omega_3} + \kappa_a\right) a_1 \quad (46)\]

The central bank can eliminate the intermediation wedge, and therefore achieve the frictionless allocation, by setting \(\kappa_b = -1\) and \(\kappa_a = -\frac{\theta_2}{\omega_3}\).

The same outcome can be achieved through a secret intervention, following the same reaction function. In fact, offsetting completely the noise-trading shock (\(\kappa_b = -1\)) makes the exchange rate signal perfectly informative, and therefore the economy reaches full information endogenously. To sum up, the central bank can achieve the frictionless equilibrium by closing the intermediation gap with either secret or public FX intervention.

**Extrapolative expectations** With extrapolative expectations it is generally not possible to close the intermediation and belief wedge simultaneously (Proposition 4). Thus a second-best problem arises in which the central bank may want to exploit the intermediation wedge in order to reduce the impact of the belief wedge. A complete characterization of this trade-off requires a welfare analysis, which we undertake next.

### 4.4 Normative analysis of FX interventions

We evaluate welfare by taking a quadratic approximation of the welfare function around the frictionless allocation (see Appendix E for a derivation). The welfare function is defined as the average expected utility across the islands of the small open economy. The optimal FX intervention policy is described by the values of \((\kappa_a, \kappa_b)\) in the central bank’s reaction function (eq. (32)) that maximize welfare under either public or secret interventions. Figure 4 reports the value of welfare relative to the frictionless benchmark under the optimal policy for an illustrative calibration and different degrees of
Figure 4: Welfare under optimal public and secret FX intervention policies

Notes: This figure reports values of different variables under optimal FX intervention policy for different levels of the over-reaction, $\delta$, and for both public and secret FXI policy, for an illustrative calibration of the model.

As per Proposition 4, for a low degree of over-extrapolation the belief wedge is minimized with full information. In this calibration, minimizing the belief wedge is (part of the) optimal policy, thus public and secret interventions are designed to reveal the state of the economy, and they achieve the same level of welfare. The state of the economy is revealed by fully offsetting noise-trading shocks so that the equilibrium exchange rate reflects only fundamentals, regardless of whether agents observe the quantity of bonds purchased by the central bank. Conditional on offsetting the noise traders, the central bank chooses $\kappa_a$ to balance over-borrowing stemming from over-extrapolation and under-borrowing stemming from intermediation frictions in the competitive equilibrium. More specifically, the optimal policy allows part of households’ borrowing demand to be reflected in higher borrowing costs (thus exploiting the intermediation wedge) to counteract the over-borrowing due to over-optimism.

Our key finding is that, for a sufficiently high degree of over-extrapolation, the

\[^{19}\text{The level of welfare is, however, lower than the one attained in the frictionless equilibrium except when } \delta = 0.\]
optimal secret FX intervention policy dominates the optimal public FX intervention policy, by leading to lower welfare losses. In this parameterization, the optimal secret policy achieves a better outcome by reducing the belief wedge via a reduction of the information content of the exchange rate (as reflected in the non-zero posterior variance of $a_1$). In fact, interventions do not completely offset noise trader demand for bonds ($\kappa_b \neq 1$) and are less responsive to productivity, overall reducing the correlation between exchange rates and fundamentals. The central bank thus strikes a balance between allowing for some inefficient capital flows driven by noise traders and keeping the information content of the exchange rate low enough to tame over-reaction. Intuitively, the optimal secret intervention achieves a superior welfare outcome because it can affect an additional margin relative to the public intervention – the informativeness of the exchange rate.\(^{20}\)

In addition, we remark that the secret FXI policy effectively reduces the equilibrium volatility of the exchange rate, relative to the public FXI policy, especially in the region of high extrapolation. Without interventions, agents’ over-reaction to the informational content of equilibrium exchange rate causes excessive volatility in macroeconomic allocations, which feeds back into the exchange rate. By letting the exchange rate reflect some non-fundamental volatility, the resulting decline in its information content acts to reduce the amplification due to over-extrapolation and, in turn, the equilibrium volatility of the exchange rate. Such feedback mechanism behind the lower equilibrium exchange rate volatility provides an intuitive rationale for the widespread empirical practices of “systematic managed floating” (Frankel, 2019).

An interesting implication of our analysis is that whether exchange rates reflect fundamental or noise is an equilibrium outcome that depends on the optimal design and communication about FX interventions. In our model, public interventions, if designed optimally, ceteris paribus should imply an exchange rate that is very tightly related to future macroeconomic conditions. On the contrary, optimally secret interventions should result in an exchange rate driven partly by noise trading (as can be seen in the bottom-left panel of Figure 4).

\(^{20}\)With the rule we consider, the public intervention always fully reveals fundamentals. In a world with more than two shocks, public FXI would not necessarily render the exchange rate fully informative. However, the distinctive feature of secret interventions is that they can make the exchange rate less informative than under no interventions, whereas the public interventions always increase or leave unchanged the information content of the exchange rate relative to no interventions.
5 Conclusions

We studied FX interventions in a macro model in which segmented financial markets and information frictions coexist. Both frictions generate wedges in aggregate consumption relative to its frictionless counterfactual, namely an intermediation wedge and a belief wedge. We formalized a novel informational role of the exchange rate in macroeconomic allocation, as agents use the exchange rate to learn about future fundamentals and make consumption and investment decisions. FX interventions can contemporaneously influence the intermediation wedge, via the standard portfolio balance channel, and the belief wedge, both by altering the information content of the exchange rate and through signaling. We highlighted that their conduct (rule-based vs discretionary) and communication (public vs secret) are important in determining the effects of FX interventions. We then discussed the challenges that a central bank faces when trying to stabilize the economy, and how possible departures from rational expectations shape the central banks’ trade-off. A conclusion of our analysis is that managing the information content of the exchange rate can be optimal if individuals overreact to available information, and this is best achieved when FXI communication is opaque.

Appendix

A Derivations

A.1 Financiers’ demand for foreign currency bonds

We follow Fanelli and Straub (2021) and assume that there exists a continuum of risk-neutral financiers, labeled by \( j \in [0, \infty) \), in each island \( i \). Financiers also hold a zero-capital portfolio in home and foreign bonds denoted \((d_{i,j}^i, 1, d_{i,j}^i, 1)\). Financier’s investment decisions are subject to two important restrictions. First, each intermediary is subject to a net open position limit of size \( D > 0 \). Second, intermediaries face heterogeneous participation costs, as in Alvarez et al. (2009). In particular, each intermediary \( j \) active in the foreign bond market at time \( t \) is obliged to pay a participation cost of exactly \( j \) per unit of foreign currency invested.\(^{21}\)

Putting these ingredients together, intermediary \( j \) on island \( i \) chooses \( d_{i,j}^i, 1 \) that solves

\[
\max_{d_{i,j}^i, 1 \in [-D, D]} d_{i,j}^i, 1 \left( R^*_0 \right) - j \left| d_{i,j}^i, 1 \right|,
\]

where \( \tilde{R}_1^i \equiv R_0^* - R_0 S_0 S_1 \) is the return on one foreign-currency unit holding expressed in foreign currency and \( E_0^i \) is the same expectation operator as the island-\( i \) household’s.

Intermediary \( j \)’s expected cash flow conditional on investing is \( D \left| E_0^i \left( \tilde{R}_1^i \right) \right| \) while participation costs are \( jD \). Thus, investing is optimal for all intermediaries \( j \in [0, \tilde{j}] \), with the marginal active intermediary \( \tilde{j} \) given by \( \tilde{j} = \left| E_0^i \left( \tilde{R}_1^* \right) \right| \). The aggregate investment volume is then

\[
\frac{D_1^*}{R_0^*} = \tilde{j} D \text{sign} \left\{ E_0^i \left( \tilde{R}_1^* \right) \right\}.
\]

Defining \( \hat{\Gamma} \equiv D^{-1} \) and substituting out \( \tilde{j} \), we obtain the total demand for foreign-currency bonds on island \( i \), \( D_1^* = \int d_{i,j}^i, 1 \, dj \):

\[
\frac{D_1^*}{R_0^*} = \frac{1}{\hat{\Gamma}} E_0^i \left( R_0^* - R_0 S_0 S_1 \right).
\]

\(^{21}\) We also assume that participation costs constitute transfers to households in the home island economy. Thus, no extra cost terms enter the household’s budget constraint.
which is equation (12) in the text.

A.2 Island-level equilibrium

The log-linearized version of the household’s optimality conditions (7), (9), and (10) are:

\[
\sigma(E_i^0c_i^1 - c_i^0) = r_0 - (E_0p_i^1 - p_i^0), \tag{A.2}
\]

\[
(1 - \alpha)k_i^1 = E_i^0(s_1 - p_i^1) + E_i^0a_1 - r_0 + (E_0^i p_i^1 - p_i^0), \tag{A.3}
\]

\[
s_t - p_i^t = -\frac{1 - \gamma}{\theta} y_{T,t}^i, \tag{A.4}
\]

Island-i budget in (11) can be combined and log-linearized as:\textsuperscript{22}

\[
\frac{1 + \phi}{\beta} y_{T,0}^i = a_1 + \alpha k_i^1 - y_{T,1}^i \tag{A.5}
\]

where \( \phi = \beta \alpha \gamma \). The final good aggregator in (3) yields:

\[
\frac{1}{1 + \phi} c_i^0 + \frac{\phi}{1 + \phi} k_i^1 = \gamma y_{T,0}^i \quad c_i^1 = \gamma y_{T,1}^i. \tag{A.6}
\]

The log-linear optimality condition of financiers (13):

\[
\Gamma \int d_i^1 \ast di = E_0 s_1 - s_0 - (r_0 - r_0^\ast) \tag{A.7}
\]

where \( d_i^1 \ast \equiv \frac{AD^i}{Y_{T,1}^i} \) and \( \Gamma \equiv \hat{\Gamma} \cdot Y_{T,1}^{ss} \cdot \beta^2 \).

Finally, bond market clearing, (17) implies:

\[
\int d_i^1 \ast di = -\frac{1 + \phi}{\beta} \int y_{T,0}^i di - n_i^\ast - f_i^\ast \tag{A.8}
\]

We also normalize the average price of the consumption basket, such that \( \int p_i^t di = 0 \), for \( t = [0, 1] \). This implies that the aggregate real exchange rate equals the nominal exchange rate, that is:

\[
q_t = s_t
\]

\textsuperscript{22}The log-linearized budget constraint is not affected by the size of the tax on financiers and noise traders’ carry-trade profits are taxed, nor on how they are distributed across islands, as these represent second-order terms.
A.3 Equilibrium exchange rate of the small open economy

Consider the following set of island-i equilibrium equations:

\[ s_0 - p^i_0 = -\frac{1 - \gamma}{\theta} y^i_{T,0} \]  (A.9)

\[ s_1 - p^i_1 = -\frac{1 - \gamma}{\theta} y^i_{T,1} \]  (A.10)

\[ r_0 - (E_0^i p^i_1 - p^i_0) = \sigma \gamma E_0^i y^i_{T,1} - (\sigma \gamma)(1 + \phi)y^i_{T,0} + \sigma \phi k^i_1 \]  (A.11)

\[ \frac{(1 + \phi)}{\beta} y^i_{T,0} = a_1 + \alpha k^i_1 - y^i_{T,1} \]  (A.12)

\[ k^i_1 = \frac{1}{1 - \alpha} E_0^i (s_1 - p^i_1) + \frac{1}{1 - \alpha} E_0^i a_1 - \frac{1}{1 - \alpha} (r_0 - (E_0^i p^i_1 - p^i_0)) \]  (A.13)

where eqs. (A.9) and (A.9) represent island-i’s demand for tradables in period 0 and 1, respectively (c.f. (A.4)); eq. (A.11) is obtained by combining the Euler equation and island-i’s resource constraint and (cf. (A.2) and (A.6)); eq (A.12) is island-i budget constraint (cf. (A.5)); (A.13) is island-i’s demand for capital (c.f. (A.3))

Using eqs (A.9)-(A.13), one can express island-i price level and tradable demand as:

\[ p^i_0 = s_0 - \frac{\omega_1}{\omega_3} \left( r_0 - (E_0^i s_1 - s_0) \right) + \frac{\omega_2}{\omega_3} E_0^i a_1 \]  (A.14)

\[ y^i_{T,0} = -\frac{\theta}{1 - \gamma} \frac{\omega_1}{\omega_3} \left( r_0 - (E_0^i s_1 - s_0) \right) + \frac{\theta}{1 - \gamma} \frac{\omega_2}{\omega_3} E_0^i a_1 \]  (A.15)

where \( \omega_1 > 0, \omega_2 > 0, \omega_3 > 0 \) are all convolution of parameters:

\[ \omega_1 \equiv [\theta \sigma \alpha \gamma (1 + \beta) + (1 - \alpha) \theta + (1 - \gamma) \alpha] \quad \omega_2 \equiv [(1 - \gamma) + \sigma \gamma \theta (1 + \alpha \beta)] \]

\[ \omega_3 \equiv \frac{\theta (1 - \alpha)(1 + \phi)}{\beta (1 - \gamma)} [\sigma \gamma \theta (1 + \beta) + (1 - \gamma)] + \theta \sigma \alpha \gamma (1 + \beta) + \theta (1 - \alpha) + (1 - \gamma) \alpha \]

Sum (A.16) across islands and use \( \int p^i_t \, di = 0 \), for \( t = [0, 1] \), to express the small-open economy (real and nominal) exchange rate as a function of average-expected
excess currency returns and average-expected TFP:

\[ q_0 = s_0 = \frac{\omega_1}{\omega_3} (r_0 - (\bar{E}_0 - s_0)) - \frac{\omega_2}{\omega_3} \bar{E}_0 a_1 \]  
(A.16)

Consider now the modified UIP condition for the small open economy bond, along with the market clearing condition in the financial market:

\[ r_0 = \bar{E}_0 s_1 - s_0 - \Gamma \left( \int d_i^* di \right) \quad \text{w/} \quad d_i^* = -n_i^* - f_i^* - \frac{(1 + \phi)}{\beta} \int y_{T,0} \, di, \]  
(A.17)

and note that, by using (A.18):

\[ \int y_{T,0} \, di = -\frac{\theta}{1 - \gamma} \frac{\omega_1}{\omega_3} (r_0 - (\bar{E}_0 s_1 - s_0)) + \frac{\theta}{1 - \gamma} \frac{\omega_2}{\omega_3} \bar{E}_0 a_1 \]  
(A.18)

Using (A.17) and (A.18), one can express the average expectation of aggregate excess home-currency returns as:

\[ r_0 - (\bar{E}_0 s_1 - s_0) = \frac{\Gamma \bar{\theta} \omega_2}{\Gamma \bar{\theta} \omega_1 + \omega_3} \bar{E}_0 a_1 + \frac{\Gamma \omega_3}{\Gamma \bar{\theta} \omega_1 + \omega_3} n_1^* + \frac{\Gamma \omega_3}{\Gamma \bar{\theta} \omega_1 + \omega_3} f_1^* \]  
(A.19)

where \( \bar{\theta} \equiv \frac{(1 + a \alpha \gamma \theta)}{\beta (1 - \gamma)} > 0. \) Use (A.19) in (A.16) across islands, we obtain the aggregate real exchange rate:

\[ q_0 = s_0 = \frac{\Gamma \omega_1}{\Gamma \bar{\theta} \omega_1 + \omega_3} (n_1^* + f_1^*) - \frac{\omega_2}{\Gamma \bar{\theta} \omega_1 + \omega_3} \bar{E}_0 a_1 \]  
(A.20)

which is the equation (18) above.

**B  The dual role of noise-trading shocks**

What fraction of exchange rate fluctuations reflects expectations of future fundamentals relative to independent noise trading? To answer this question, Figure A.1 reports the decomposition of the exchange rate into the part that reflects expectations about future fundamentals \( E_0(a_1) \), and the part that is due to noise trading \( n_1^* \) (see eq. (18)).

Under common information (\( \sigma_v = 0 \) or \( \sigma_v = \infty \)), we observe that there is a clear demarcation between \( E_0(a_1) \) and \( n_1^* \). Under full information (\( \sigma_v = 0 \)), agents can perfectly separate fundamental shocks from noise-trading shocks, and thus exchange rate fluctuations can be unequivocally attributed to either \( E_0(a_1) \) or \( n_1^* \). Under no
information \((\sigma_v = \infty)\), all the variation in \(q_0\) inevitably reflects only noise-trading shocks, since agents have no advance information about \(a_1\).

However, when information is dispersed \((\sigma_v \in (0, 1))\) and thus agents learn from the exchange rate \((I_R > 0)\) the distinction between \(E_0(a_1)\) and \(n_1^*\) is blurred: the exchange rate is a public signal, and noise-trading demand is the noise in the public signal, blurring the relationship between expectations of fundamentals and their subsequent realization. In fact, noise-trading shocks have a dual role in models where the exchange rate is a public signal (Bacchetta and Wincoop, 2006): they affect the exchange rate by altering the balance sheet position of financiers, and, by affecting the exchange rate, they also influence agents’ expectations of \(a_1\). As a result, the portion of fluctuations in \(E_0(a_1)\) due to \(a_1\) result in subsequent changes in \(a_1\), while the portion of fluctuations in \(E_0(a_1)\) due to \(n_1^*\) are not associated with subsequent changes in \(a_1\). Relatedly, because of this dual role of \(n_1^*\), there is an interaction between the pure noise-trading effect and the effect of noise trading that operates through it being the noise in the public signal \((E_0(a_1)\) due to \(n_1^*)\), as depicted in Figure A.1.

**Figure A.1: Decomposition of the exchange rate variance for different degrees of dispersed information**

<table>
<thead>
<tr>

</thead>
<tbody>
<tr>
<td><strong>E_0(a_1) due to a_1</strong></td>
<td><strong>E_0(a_1) due to n_1^</strong>*</td>
</tr>
<tr>
<td><strong>n_1^</strong>*</td>
<td><strong>n_1^</strong>*</td>
</tr>
</tbody>
</table>

*Notes:* This figure reports the decomposition of the exchange rate variation for different levels of the noise in private signal, \(\sigma_v\), under laissez faire. The rest of parameters are set as follows: \(\beta = 0.99\), \(\alpha = 0.3\), \(\gamma = 0.3\), \(\theta = 1\), \(\sigma = 1\). The standard deviation of \(a_1\) is \(\sigma_a = 3\), while the standard deviation of \(n_1^*\) is \(\sigma_n = 3\). In this figure, the over-reaction parameter, \(\delta = 0\).

Our model aligns with the empirical findings of Chahrour et al. (2022) about the source of fluctuations in the USD exchange rate. They reveal that a substantial portion
of the exchange rate variation can be attributed to both correctly anticipated changes in productivity and expectational “noise,” which influences expectations of productivity but not the actual realization. Our model aligns well with these findings, provided that information is dispersed ($\sigma_v > 0$), and thus agents learn from exchange rates, and thus offers a novel insight into the empirical relationship between exchange rates and macroeconomic fundamentals.

C  Exogenous FX intervention

Assume now that the FX interventions follow a random process, i.e. $f_1^* = \varepsilon_1^*$ with $\varepsilon_1^* \sim N(0, \beta_\varepsilon^{-1})$. While we acknowledge that in practice central banks do not follow a completely random FX intervention rule, this case is useful to build intuition and illustrates how FX interventions affect the information content of the exchange rate.\textsuperscript{23} In this case, the equilibrium exchange rate is determined according to:

$$q_0 = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} (n_1^* + \varepsilon_1^*) - \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \bar{E}_0 a_1. \quad (A.21)$$

Equation (A.21) shows that exogenous FX interventions represent an additional, exogenous shock to the foreign exchange market.

C.1  Public exogenous FX intervention

Let us first consider the case in which agents are able to observe the aggregate volume of the FX intervention, $\varepsilon_1^*$. Guess a linear solution for the (perceived) exchange rate process:

$$\hat{q}_0 = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} f_1^* + \lambda_\alpha a_1 + \lambda_\beta n_1^*, \quad (A.22)$$

where $f_1^* = \varepsilon_1^*$. Define $\hat{q}_0 \equiv \hat{q}_0 - \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} f_1^*$, as the equilibrium exchange, after the effect of the FX intervention is “partialed out.” Agents use the exchange rate as signal

$$\frac{\hat{q}_0}{\lambda_\alpha} = a_1 + \frac{\lambda_\beta}{\lambda_\alpha} n_1^*, \quad (A.23)$$

\textsuperscript{23}That said, we note that many central banks do not currently conduct FX interventions according to a rule (Patel and Cavallino, 2019).
with a error variance of $\beta_q^{-1} \equiv \frac{1}{\Lambda^2} \beta_n^{-1}$ with $\Lambda \equiv \frac{\lambda^2}{\bar{\lambda}}$, the same as in the laissez-faire economy (24). Following the same solution method as in section 2.3, one reaches the same equilibrium $\lambda_a$ and $\lambda_b$ as in (26).

**Corollary 6** (Public exogenous FX intervention). *Suppose the central bank adopts a public exogenous FX intervention rule, i.e. $f^*_1 = \varepsilon^*_1$ and $f^*_1$ is directly observed. A more volatile FX intervention does not affect the relative information content of the exchange rate $I_R$ nor the overall agents’ posterior accuracy about fundamental $D$. The equilibrium perceived exchange rate process is given by (A.22) with the same $\lambda_a$ and $\lambda_b$ as in the laissez-faire equilibrium (26).*

Since the intervention is public, agents can partial out the intervention from the exchange rate when they solve their signal extraction problem. It follows that the intervention does not affect the information content of the exchange rate. Moreover, since the intervention is random, it only adds non-fundamental variation to the exchange rate. Substituting the actual average belief in (A.21), one gets the actual exchange rate

$$q_0 = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} f_1^* + (1 + \delta) \lambda_a a_1 + \lambda_b n_1^*,$$

(A.24)

### C.2 Secret exogenous FX intervention

Consider now the case in which the central bank does not reveal the aggregate volume of the FX intervention. Notice that the intervention $\varepsilon^*_1$ and the noise shock $n_1^*$ are both unobservable exogenous shocks to the exchange rate (A.21). Guess a linear solution for the perceived exchange rate process

$$\tilde{q}_0 = \lambda_a a_1 + \lambda_b (n_1^* + \varepsilon^*),$$

(A.25)

Agents use the exchange rate as signal

$$\frac{\tilde{q}_0}{\lambda_a} = a_1 + \frac{\lambda_b}{\lambda_a} (n_1^* + \varepsilon^*),$$

(A.26)

with a error variance of $\beta_q^{-1} \equiv \frac{1}{\Lambda^2}(\beta_n^{-1} + \beta_{\varepsilon}^{-1})$ with $\Lambda \equiv \frac{\lambda^2}{\bar{\lambda}}$. Since the FX intervention is unobserved, it increases non-fundamental volatility to the exchange rate similarly to the liquidity demand from noise traders, and therefore decreases the information
content of the exchange rate $\mathcal{I}_R$.24

**Proposition 5** (Secret exogenous FX intervention). *Suppose the central bank adopts a secret discretionary FX intervention, i.e. $f_1^* = \varepsilon_1^*$ and $f_1^*$ is not directly observed. A more volatile FX intervention decreases the relative information content of the exchange rate $\mathcal{I}_R$ and agents’ posterior accuracy about fundamental $D$. The equilibrium perceived exchange rate process is given by (A.25) with $\lambda_a$ and $\lambda_b$ described in Appendix D.*

*Proof. See Appendix D.*

Proposition 5 reveals that, when implemented secretly, FX interventions have an information effect. In particular, secret exogenous FX interventions alter agents’ expectations of fundamentals by reducing the informativeness of the exchange rate. Substituting the actual average belief in (A.21), one gets the actual exchange rate

$$q_0 = (1 + \delta)\lambda_a a_1 + \lambda_b(n_1^* + \varepsilon_1^*). \quad \text{(A.27)}$$

### D Proofs

**Proof of Proposition 3.** Consider the equilibrium exchange rate in case of full information, $\bar{E}_0 a_1 = a_1$ (but with intermediation friction, $\Gamma > 0$)

$$q_0^{FI} = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} (n_1^* + f_1^*) - \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} a_1 \quad \text{(A.28)}$$

Take the difference between (18) and (A.28), and the difference between (A.28) and (42). Sum them and get

$$q_0 - q_0^{FB} = \frac{1}{\Gamma \theta \omega_1 + \omega_3} \left( \Gamma \omega_1 \left[ (n_1^* + f_1^*) + \frac{\theta \omega_2}{\omega_3} a_1 \right] - \omega_2 (\bar{E}_0 a_1 - a_1) \right) \quad \text{(A.29)}$$

24In addition to directly increasing exchange rate non-fundamental volatility, higher FX intervention volatility also decreases the load of exchange rate on non-fundamental shock $\Lambda^2$. This second effect dampens the initial decrease in exchange rate informativeness $\mathcal{I}_R$, but it cannot reverse it. Intuitively, as the exchange rate becomes less accurate, agents put more weight on their own private signals. As a consequence, the exchange rate can now aggregate more private information and becomes therefore more accurate, attenuating the initial decline in accuracy.
Substitute (A.4), (A.7), and (A.8) in (A.3) to get

$$k_1 = \frac{1}{1-\alpha} q_0 + \frac{1}{1-\alpha} E_0 a_1 - \frac{\bar{\Gamma}}{1-\alpha} \left( -\frac{1}{\beta} \frac{\theta(1+\phi)}{1-\gamma} q_0 + (n_1^* + f_1^*) \right)$$  \hfill (A.30)

Consider the frictionless investment allocation, i.e. with $\Gamma = 0$ and $\bar{E}_0 a_1 = a_1$

$$k_{1FB} = \frac{1}{1-\alpha} q_{0FB} + \frac{1}{1-\alpha} a_1$$  \hfill (A.31)

Take the difference and get

$$k_1 - k_{1FB} = \frac{1}{1-\alpha} (q_0 - q_{0FB}) + \frac{1}{1-\alpha} (E_0 a_1 - a_1) - \frac{\bar{\Gamma}}{1-\alpha} \left( -\frac{1}{\beta} \frac{\theta(1+\phi)}{1-\gamma} q_0 + (n_1^* + f_1^*) \right)$$  \hfill (A.32)

Using (18)

$$k_1 - k_{1FB} = \frac{1}{1-\alpha} \left( E_0 a_1 - a_1 \right) + \frac{1}{1-\alpha} (q_0 - q_{0FB}) + \frac{\bar{\Gamma}}{1-\alpha} \left( \bar{\theta} \frac{\Gamma \omega_1}{\Gamma \theta_1 + \omega_4} - 1 \right) (n_1^* + f_1^*) - \frac{\bar{\Gamma} \omega_2}{1-\alpha} \frac{\bar{\theta} \omega_1}{\bar{\Gamma} \theta_1 + \omega_3} E_0 a_1$$

$$k_1 - k_{1FB} = \frac{1}{1-\alpha} \left( E_0 a_1 - a_1 \right) + \frac{1}{1-\alpha} (q_0 - q_{0FB}) + \frac{\bar{\Gamma}}{1-\alpha} \left( \bar{\theta} \frac{\Gamma \omega_1}{\Gamma \theta_1 + \omega_4} - 1 \right) (n_1^* + f_1^*) - \frac{\bar{\Gamma} \omega_2}{1-\alpha} \frac{\bar{\theta} \omega_1}{\bar{\Gamma} \theta_1 + \omega_3} a_1$$

$$k_1 - k_{1FB} = \frac{1}{1-\alpha} (q_0 - q_{0FB}) + \frac{\bar{\Gamma}}{1-\alpha} \left( \bar{\theta} \omega_2 \frac{\Gamma \omega_3}{\bar{\theta} \omega_3 a_1} \right) - \left[ \theta \Gamma (\theta_1 - \omega_2) + \omega_3 \right] \left( E_0 a_1 - a_1 \right) \hfill (A.33)$$

First, consider the case $\theta \neq \sigma$, which implies $\omega_1 \neq \omega_2$. Suppose the belief wedge $(E_0 a_1 - a_1) \neq 0$. Then the exchange rate is optimal $q_0 = q_{0FB}$ only if

$$\frac{\Gamma \omega_2}{\beta(1-\gamma)\omega_4} [\beta(1-\gamma)\omega_4 (n_1^* + f_1^*) + \theta \omega_3 a_1] = \omega_3 (E_0 a_1 - a_1).$$

However, in that case investment is not at optimum, $k_1 \neq k_{1FB}$. Therefore, both capital and investment can’t be simultaneously at optimum if $(E_0 a_1 - a_1) \neq 0$.

Second, consider the case $\theta = \sigma$, which implies $\omega_1 = \omega_2$. In this case, one can write
the wedge in capital accumulation solely as a function of the wedge in exchange rate.

\[ k_1 - k_1^{FB} = \frac{1}{1-\alpha} \left( \frac{\omega_2 - \omega_3}{\omega_2} \right) (q_0 - q_0^{FB}) \]  

(A.34)

In this case, if the exchange rate equals the frictionless value, so does the capital accumulation. As a result, it is sufficient to have \( \Gamma \left[ (n_1^* + f_1^*) + \frac{\delta \omega_2}{\omega_2} a_1 \right] - (\bar{E}_0 a_1 - a_1) = 0 \) to obtain the frictionless allocation, even if \( \bar{E}_0 a_1 - a_1 \neq 0 \)

\[ \square \]

**Proof of Proposition 1.** Plug (25) in the solution for the perceived exchange rate process (22):

\[ q_0 = \left[ 1 + \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_q}{D a_1} \right]^{-1} \left\{ \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} n_1^* - \left[ \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_v}{a_1} \right] a_1 \right\} \]  

(A.35)

To find the undetermined coefficients, set (A.44) equal to the guess (23). You get

\[ -\frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} (1 + \delta) \frac{\beta_v}{D} = \lambda_a \left[ 1 + \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_q}{D a_1} \right] \]  

\[ \lambda_a = -\frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_v}{\beta_v + \beta_q} \]  

(A.36)

and

\[ \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} = \lambda_b \left[ 1 + \frac{\omega_2}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_q}{D a_1} \right] \]  

\[ \lambda_b = \frac{\Gamma \omega_1}{\Gamma \theta \omega_1 + \omega_3} \frac{\beta_v + \beta_q}{\beta_v} \]  

(A.37)

Take the ratio

\[ \frac{\lambda_a}{\lambda_b} = -\frac{\omega_2}{\Gamma \omega_1} \frac{\beta_v}{D} \]  

(A.38)

Define \( \Lambda \equiv \frac{\lambda_a}{\lambda_b} \). Then:

\[ \Lambda = -\frac{\omega_2}{\Gamma \omega_1} \frac{\beta_v}{\beta_v + \beta_a + \Lambda^2 \beta_n} \]  

\[ \Lambda^3 + \left( \frac{\beta_v}{\beta_n} + \frac{\beta_a}{\beta_n} \right) \Lambda + \frac{\omega_2}{\Gamma \omega_1} \frac{\beta_v}{\beta_n} = 0 \]  

(A.39)
Define $\rho_1 \equiv \frac{(\beta_v + \beta_a)}{\beta_n}$ and $\rho_2 \equiv \frac{\omega_2}{\Gamma \omega_1 \beta_n}$. Thus, rewrite (A.52) as:

$$A^3 + \rho_1 A + \rho_2 = 0 \quad (A.40)$$

Cubics of this form are said to be “depressed.” Cardano’s formula states the following. If

1. the cubic equation is of the form in (A.53)
2. $\rho_1$ and $\rho_2$ are real numbers
3. $\frac{\rho_2^2}{4} + \frac{\rho_3^2}{27} > 0$ (which is satisfied in our context for any real value of $\frac{\omega_a}{\Gamma \omega_2}$)

Then, equation (A.53) has:

(i) the real root:

$$\sqrt[3]{-\frac{\rho_2}{2} + \sqrt{\frac{\rho_2^2}{4} + \frac{\rho_3^2}{27}}} + \sqrt[3]{-\frac{\rho_2}{2} - \sqrt{\frac{\rho_2^2}{4} + \frac{\rho_3^2}{27}}} \quad (A.41)$$

(ii) and two other roots that are non-real complex conjugate numbers.

Proof of Proposition 4. Take the limit of (45),

$$\lim_{\beta_q \to \infty} \text{var}(E_0' a_1 - a_1) = \delta^2 \frac{1}{\beta^a}$$

$$\lim_{\beta_q \to 0} \text{var}(E_0' a_1 - a_1) = \frac{(\delta \beta^v - \beta^a)^2 \frac{1}{\beta^a} + (1 + \delta)^2 \beta^v}{(\beta^v + \beta^a)^2} \quad (A.42)$$

As a result, $\lim_{\beta_q \to \infty} \text{var}(E_0' a_1 - a_1) < \lim_{\beta_q \to 0} \text{var}(E_0' a_1 - a_1)$ if $\delta < 1$.

Moreover,

$$\frac{\partial \text{var}(E_0' a_1 - a_1)}{\partial \beta_q} = \frac{1}{(\beta^v + \beta^a)^3} \left\{(\beta^v + \beta^a)[1 - 2(1 + \delta)] - \beta^q[1 - 2\delta(1 + \delta)]\right\} \quad (A.43)$$

we can distinguish two cases. If $[1 - 2\delta(1 + \delta)] > 0 \iff \delta < -\frac{1+\sqrt{3}}{2}$, then $\frac{\partial \text{var}(E_0' a_1 - a_1)}{\partial \beta_q} < 0$, so the belief wedge decline in public signal accuracy. If $[1 - 2\delta(1 + \delta)] < 0 \iff \delta > \frac{1+\sqrt{3}}{2}$, then $\frac{\partial \text{var}(E_0' a_1 - a_1)}{\partial \beta_q} < 0$ as long as $0 < \beta_q < (\beta_a + \beta_v) \frac{1-2(1+\delta)}{(1-2\delta(1+\delta))}$ and $\frac{\partial \text{var}(E_0' a_1 - a_1)}{\partial \beta_q} > 0$ as long as $(\beta_a + \beta_v) \frac{1-2(1+\delta)}{(1-2\delta(1+\delta))} < \beta_q < \infty$. 

48
As a result, if $\delta < \frac{-1+\sqrt{3}}{2}$ the global minimum is reached at $\beta \to \infty$. if $\delta > \frac{-1+\sqrt{3}}{2}$, the global minimum is reached at $\beta_q = (\beta_a + \beta_v)^\frac{1-2(1+\delta)}{1-2(1+\delta)}$.

Proof of Proposition 2. Plug (25) in the solution for the exchange rate (37):

$$q_0 = \left[1 + \frac{\omega_2 - \Gamma\omega_1 \tilde{\kappa}_a}{\Gamma \theta_1 + \omega_3} (1 + \delta) \frac{\beta_v}{D \lambda_a}\right]^{-1} \left\{ -\frac{\Gamma\omega_1}{\Gamma \theta_1 + \omega_3} (1 + \tilde{\kappa}_b) n_1^* - \left[\frac{\omega_2 - \Gamma\omega_1 \tilde{\kappa}_a}{\Gamma \theta_1 + \omega_3} (1 + \delta) \frac{\beta_v}{D}\right] a_1 \right\}$$

(A.44)

To find the undetermined coefficients, set (A.44) equal to the guess (23). You get

$$\lambda_a = -\frac{\omega_2 - \Gamma\omega_1 \tilde{\kappa}_a}{\Gamma \theta_1 + \omega_3} (1 + \delta) \frac{\beta_v + \beta_q}{D}$$

(A.45)

and

$$\lambda_b = \frac{\Gamma\omega_1}{\Gamma \theta_1 + \omega_3} (1 + \tilde{\kappa}_b) \frac{\beta_v + \beta_a}{\beta_v}$$

(A.46)

Take the ratio

$$\frac{\lambda_a}{\lambda_b} = \frac{\omega_2 - \Gamma\omega_1 \tilde{\kappa}_a}{\Gamma \omega_1 (1 + \tilde{\kappa}_b)} (1 + \delta) \frac{\beta_v}{D}$$

(A.47)

Define $\Lambda \equiv \frac{\lambda_a}{\lambda_b}$. Then:

$$\Lambda = -\frac{\omega_2}{\Gamma \omega_1} (1 + \delta) \frac{\beta_v}{\beta_a + \Lambda^2 \beta_n}$$

(\text{A.48})

$$\Lambda^3 + \left(\frac{\beta_v}{\beta_n} + \frac{\beta_a}{\beta_n}\right) \Lambda + \frac{\omega_2 - \Gamma\omega_1 \tilde{\kappa}_a}{\Gamma \omega_1 (1 + \tilde{\kappa}_b)} (1 + \delta) \frac{\beta_v}{\beta_n} = 0$$

Define $\rho_1 \equiv \frac{(\beta_v + \beta_a)}{\beta_n}$ and $\rho_2 \equiv \frac{\omega_2 - \Gamma\omega_1 \tilde{\kappa}_a}{\Gamma \omega_1 (1 + \tilde{\kappa}_b)} (1 + \delta) \frac{\beta_v}{\beta_n}$. Thus, rewrite (A.52) as:

$$\Lambda^3 + \rho_1 \Lambda + \rho_2 = 0$$

(A.49)

Applying the Cardano’s formula as in Proposition 1, one gets the following unique solution:

$$\sqrt[3]{-\rho_2} + \sqrt[3]{\rho_2} + \sqrt[3]{\rho_2} + \sqrt[3]{\rho_2} - \sqrt[3]{\rho_2} + \sqrt[3]{\rho_2}$$

(A.50)

Proof of Proposition 5. Following the proof for Proposition 1, Plug (25) in the solution
for the exchange rate (22) and get the equilibrium λs

\[ \lambda_a = -\frac{\omega_2}{\Gamma \omega_1 + \omega_3} \left( \frac{\beta_v + \beta_a}{\beta_v + \beta_q} \right) \]
\[ \lambda_b = \frac{\omega_2}{\Gamma \omega_1 + \omega_3} \left( \frac{\beta_v + \beta_q}{\beta_v} \right) \]  

(A.51)

Define \( \Lambda \equiv \frac{\lambda_a}{\lambda_b} \). Then, since \( \beta_q \equiv \Lambda^2 (\beta_n^{-1} + \beta_\varepsilon^{-1})^{-1} \):

\[ \Lambda = -\frac{\omega_2}{\Gamma \omega_1} \frac{\beta_v}{\beta_v + \beta_a + \Lambda^2 (\beta_n^{-1} + \beta_\varepsilon^{-1})^{-1}} \]
\[ \Lambda^3 + \left( \frac{\beta_v + \beta_a}{(\beta_n^{-1} + \beta_\varepsilon^{-1})^{-1}} \right) \Lambda + \frac{\omega_2}{\Gamma \omega_1} \frac{\beta_v}{(\beta_n^{-1} + \beta_\varepsilon^{-1})^{-1}} = 0 \]  

(A.52)

Define \( \rho_1 \equiv \frac{(\beta_v + \beta_a)}{(\beta_n^{-1} + \beta_\varepsilon^{-1})^{-1}} \) and \( \rho_2 \equiv \frac{\omega_2}{\Gamma \omega_1} \frac{\beta_v}{(\beta_n^{-1} + \beta_\varepsilon^{-1})^{-1}} \). Thus, rewrite (A.52) as:

\[ \Lambda^3 + \rho_1 \Lambda + \rho_2 = 0 \]  

(A.53)

Applying the Cardan’s formula as in Proposition 1, one gets the following unique solution:

\[ \sqrt[3]{-\frac{\rho_2}{2} + \sqrt{\frac{\rho_2^2}{4} + \rho_1^3}} + \sqrt[3]{-\frac{\rho_2}{2} - \sqrt{\frac{\rho_2^2}{4} + \rho_1^3}} \]  

(A.54)

\( \square \)

E Welfare Approximation

We evaluate welfare using an utilitarian criterion in which every island of the small open economy receives the same Pareto weight. Welfare is therefore defined as:

\[ W = \int EW_i di = \int E \left[ \frac{C_i^{1-\sigma}}{1-\sigma} + \beta \left( \frac{C_i^{1-\sigma}}{1-\sigma} \right) \right] di. \]  

(A.55)

We consider a second-order approximation of the above welfare function around the steady state of the frictionless economy, meaning with no intermediation frictions \( \Gamma = 0 \) and with perfect information \( E_0^i a_1 = a_1 \):

\[ W_i = C^{1-\sigma} \left\{ \hat{c}_0 + \frac{1}{2}(1-\sigma)(\hat{c}_0^i)^2 \right\} + \beta \hat{c}_1 + \frac{1}{2}(1-\sigma)(\hat{c}_1^i)^2 \} + t.i.p. + O(||\xi||^3), \]  

(A.56)
where hatted variables are expressed in log-deviations from steady state, \(t.i.p.\) stands for terms independent of policy, and \(\mathcal{O}(||\epsilon||^3)\) denotes terms that are of third or higher order. Utility is maximized when consumption takes on its efficient values

\[
W^{\text{max}} \approx [\bar{c}_0 + \frac{1}{2}(1 - \sigma)c_0^2] + \beta[\bar{c}_1 + \frac{1}{2}(1 - \sigma)c_1^2]
\]  
(A.57)

where barred variables are log-deviations from the steady state in the efficient allocation (which is the same for every island). In general, this maximum may not be attainable. We can write \(\hat{x}_t = \bar{x}_t + \tilde{x}_t\) so that \(\tilde{x}_t = \hat{x}_t - \bar{x}_t\) represents gaps from the efficient allocation. We then have:

\[
W_i - W^{\text{max}} \approx \hat{c}_0 + \beta \hat{c}_1 + \frac{1}{2}(1 - \sigma)(\hat{c}_0^2 - c_0^2) + \beta \frac{1}{2}(1 - \sigma)(\hat{c}_1^2 - c_1^2)
\]  
(A.58)

To eliminate the linear terms in (A.58), we characterize \(C_0\) and \(C_1\) by taking a second-order approximation of the equilibrium market clearing conditions in (3). To lighten notation we drop the \(i\) subscript in the following derivations. Starting from \(C_1\), we obtain:

\[
\hat{c}_1 + \frac{1}{2} \hat{c}_1^2 = \gamma \hat{y}_{T,1} + \frac{1}{2} \gamma (\gamma + \theta - 1) \hat{y}_{T,1}^2
\]

Now square the first-order approximation:

\[
c_1^2 = \gamma^2 \hat{y}_{T,1}^2
\]

to get rid of \(\hat{c}_1^2\) above and obtain:

\[
\hat{c}_1 = \gamma \hat{y}_{T,1} + \frac{1}{2} \gamma (1 - \gamma) \frac{\theta - 1}{\theta} \hat{y}_{T,1}^2
\]  
(A.59)

Similarly for \(c_0\), the second-order approximation of (3) yields:

\[
\hat{c}_0 + \frac{1}{2} c_0^2 + \phi (\hat{k}_1 + \frac{1}{2} \hat{k}_1^2) = (1 + \phi) \gamma \hat{y}_{T,0} + \frac{1}{2} (1 + \phi) \gamma \frac{\gamma (\gamma + \theta - 1) \hat{y}_{T,0}^2}{\theta}
\]

Once again, use the square of the first-order approximation:

\[
c_0^2 = \phi^2 \hat{k}_1^2 + (1 + \phi)^2 \gamma \hat{y}_{T,0}^2 - 2 \gamma (1 + \phi) \phi \hat{k}_1 \hat{y}_{T,0}
\]  
(A.61)

51
to get rid of \( c_0^2 \) above and obtain, after some manipulations,

\[
\hat{c}_0 = \gamma(1+\phi)\hat{y}_{T,0} - \phi k_1 - \frac{1}{2}\phi(1+\phi)\hat{k}_1^2 + \frac{1}{2}\xi\hat{y}_{T,0}^2 + \gamma(1+\phi)\phi \hat{k}_1 \hat{y}_{T,0}. \quad (A.62)
\]

where we defined \( \xi = (1+\phi)\gamma \left[(1-\gamma)\frac{\theta-1}{\theta} - \gamma\phi \right] \). Now we consolidate the budget constraints in (A.59) imposing \( \tau = 1 \):

\[
Y_{T,1} = \frac{1}{\beta}K_0^\alpha - \frac{1}{\beta}Y_{T,0} + A_1 K_1^\alpha \quad (A.63)
\]
to obtain a second-order approximation for \( Y_{T,1} \)

\[
\hat{y}_{T,1} + \frac{1}{2}\gamma^2 = -\frac{1}{\beta}(1+\phi)\left(\hat{y}_{T,0} + \frac{1}{2}\hat{y}_{T,0}^2\right) + \left(\hat{\alpha}_1 + \alpha \hat{k}_1 + \frac{1}{2}\left(\alpha^2 \hat{k}_1^2 + 2\alpha \hat{\alpha}_1 \hat{k}_1 + \hat{a}_1^2\right)\right)
\]

and substitute it into (A.59) and simplify to obtain:

\[
\hat{c}_1 = -\gamma \frac{1}{\beta}(1+\phi)\hat{y}_{T,0} + \gamma \hat{\alpha}_1 + \gamma \alpha \hat{k}_1 + \frac{\gamma}{2} \left\{ \alpha^2 \hat{k}_1^2 + 2\alpha \hat{\alpha}_1 \hat{k}_1 + \hat{a}_1^2 - \frac{(1+\phi)}{\beta} \hat{y}_{T,0}^2 \right\}
+ \frac{1}{2} \gamma \left[ (1-\gamma)\frac{\theta-1}{\theta} - 1 \right] \hat{y}_{T,1}^2
\]

Multiply the above expression by \( \beta \) to obtain:

\[
\beta \hat{c}_1 = -\gamma(1+\phi)\hat{y}_{T,0} + \gamma \beta \hat{\alpha}_1 + \gamma \alpha \beta \hat{k}_1 + \frac{\beta \gamma}{2} \left\{ \alpha^2 \hat{k}_1^2 + 2\alpha \hat{\alpha}_1 \hat{k}_1 + \hat{a}_1^2 - \frac{(1+\phi)}{\beta} \hat{y}_{T,0}^2 \right\}
+ \frac{1}{2} \beta \gamma \left[ (1-\gamma)\frac{\theta-1}{\theta} - 1 \right] \hat{y}_{T,1}^2 \quad (A.64)
\]

Then use (A.62) and (A.64) to evaluate \( \hat{c}_0 + \beta \hat{c}_1 = (\hat{c}_0 - \hat{c}_0) + \beta(\hat{c}_1 - \hat{c}_1) \):

\[
\hat{c}_0 + \beta \hat{c}_1 = -\frac{\phi}{2}(1+\phi-\alpha)(\hat{k}_1^2 - \bar{k}_1^2) + \frac{1}{2}(\xi-\beta \gamma \frac{1+\phi}{\beta})(\hat{y}_{T,0}^2 - \bar{y}_{T,0}^2) + \gamma(1+\phi)\phi(\bar{k}_1 \hat{y}_{T,0} - \hat{k}_1 \bar{y}_{T,0}) + \\
+ \phi \hat{\alpha}_1(\hat{k}_1 - \bar{k}_1) + \frac{1}{2} \beta \gamma \left[ (1-\gamma)\frac{\theta-1}{\theta} - 1 \right] (\hat{y}_{T,1}^2 - \bar{y}_{T,1}^2) \quad (A.65)
\]
Finally, substitute (A.65) in (A.58) to eliminate linear terms from the welfare expression:

\[ W - W^{max} \approx -\phi \frac{1}{2} (1 + \phi - \alpha) (\hat{k}_2^2 - \bar{k}_1^2) + \frac{1}{2} (\xi - \beta \gamma \frac{(1 + \phi)}{\beta} ) (\hat{y}_{T,0}^2 - \bar{y}_{T,0}^2) \]

\[ + \gamma (1 + \phi) \phi (\hat{k}_1 \hat{y}_{T,0} - \bar{k}_1 \bar{y}_{T,0}) + \phi \hat{a}_1 (\hat{k}_1 - \bar{k}_1) + \frac{1}{2} \beta \gamma \left[ (1 - \gamma) \frac{\theta - 1}{\theta} - 1 \right] (\hat{y}_{T,1}^2 - \bar{y}_{T,1}^2) \]

\[ + \frac{1}{2} (1 - \sigma) (\hat{c}_0^2 - \bar{c}_0^2) + \beta \frac{1}{2} (1 - \sigma) (\hat{c}_1^2 - \bar{c}_1^2) \]  

(A.66)

Equation (A.66) is the expression we use in all our welfare-related calculations and results.
